Kirsch et al. developed a novel prediction tool, the Vesicoureteral Reflux Index (VURI), a validated tool that incorporates timing of reflux, presence of associated anomalies, sex, and VUR grade to predict complete or partial resolution of reflux by at least two grades. It has been validated for children younger than and older than 24 months of age (Kirsch et al., 2014; Garcia-Roig et al., 2017). Cooper et al. also looked at the ratio of ureteric diameter, normalized to the L1–L3 vertebral body distance. They found that the ratio correlated with VUR grade and that the higher the ureteral diameter ratio the lower the likelihood of spontaneous resolution (Cooper et al., 2015; Arlen et al., 2017).

The volume at which VUR occurs on cystography was also found to be a useful predictor of reflux resolution. When reflux occurred at greater than 75% of predicted bladder capacity, it was significantly more likely to resolve spontaneously than if VUR occurred at lower volumes (McMillan et al., 2006).

These tools allow for counseling practitioners and families on more direct indications for both reflux intervention or relaxing follow-up, including a reconsideration of the ongoing need for prophylactic antibiotics. **Because the consequences of reflux pose the greatest threat, the ability to predict them rather than predict reflux persistence or resolution may be more clinically relevant.**

Resolution by Age

The age at which reflux begins or is first encountered will play a more important role in the management of the patient with reflux than the grade itself. It is self-evident that if reflux is a congenital disorder with an inherent tendency to resolve spontaneously over time, it will be most prevalent in neonates and young children and demonstrate the greatest tendency to resolve in this group. Conversely, in any analysis, if reflux is truly primary, is encountered in an older child, and has been present since birth, it already has demonstrated a propensity to persist and therefore is self-selected for reflux that is unlikely to resolve (Skoog et al., 1987). The initial 1997 AUA guidelines provided a synthesis of large numbers and reasonable statistical estimates of resolution rates segregated by age and grade (Elder et al., 1997) (Fig. 29.18). Subsequent revisions of the guidelines in 2010, which were again validated in 2017, provide a similar picture for resolution rates of VUR and refocus the importance of identifying patients that would benefit from screening based on several potential risk factors, beyond age.

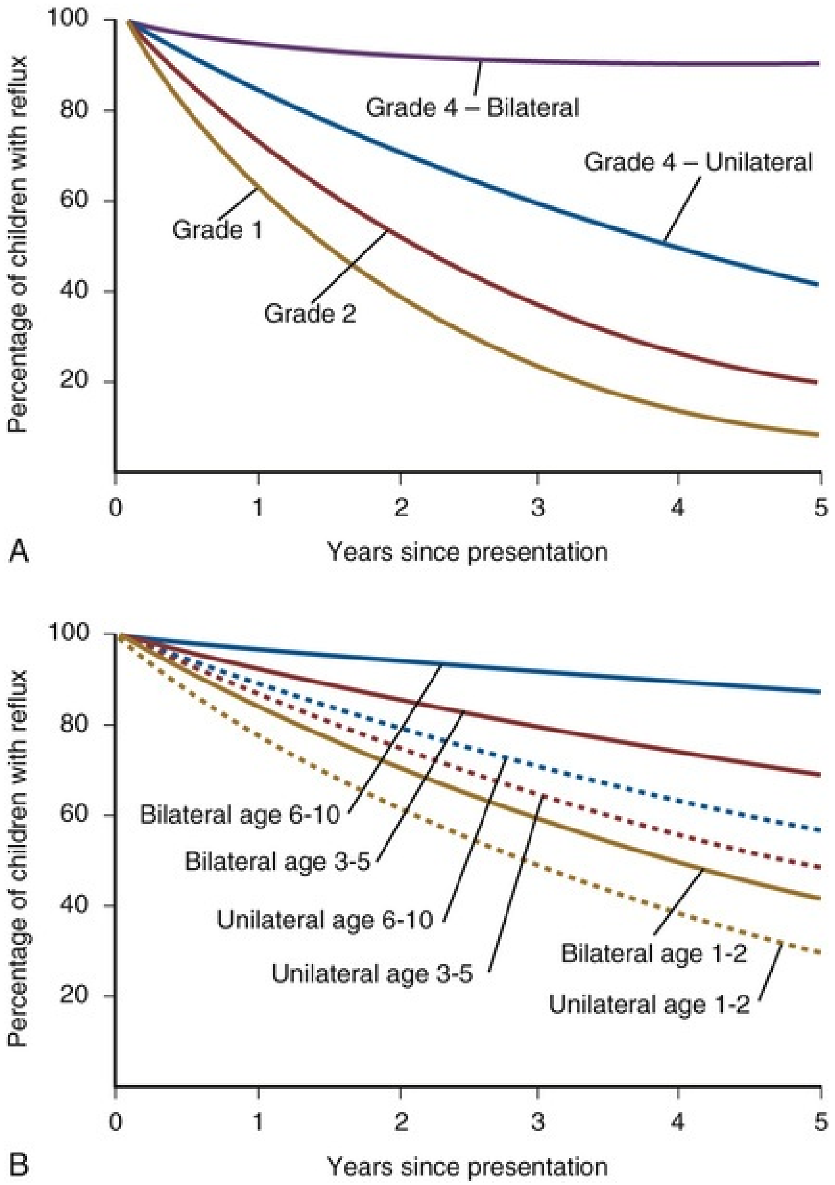

FIG. 29.18 (A) Percent chance of persistence of grades 1, 2, and 4 reflux for 1 to 5 years after initial evaluation. (B) Percent chance of persistence of grade 3 reflux by age for 1 to 5 years after initial evaluation. (Data from Elder JS, Peters CA, Arant BS Jr, et al. Pediatric Vesicoureteral Reflux Guidelines Panel summary report on the management of primary vesicoureteral reflux in children. *J Urol*. 1997;157[5]:1846–1851.)

Interpretation of other large studies suggest that diagnosis at 5 years of age and in infancy is associated with a similar resolution rate (20% per year), regardless of age (Connolly et al., 2001). However, as stated at the outset, it must be remembered that resolution 5 years after 5 years of age implies reflux has required 10 years to resolve versus resolution 5 years after birth. Moreover, the observation by McLorie et al. that high-grade reflux in patients presenting after birth showed no difference in resolution rates between subjects younger and older than 1 year of age may reflect the generally poor resolution rate of high-grade reflux to begin with (McLorie et al., 1990). The study by Skoog et al. observed that 30% to 35% of subjects resolved their reflux each year (Skoog et al., 1987). Reflux in younger patients (<12 months of age) resolved more quickly (1.44 vs. 1.85 years, $P < .02$), with grade 3 requiring slightly more time than grade 2 to resolve (1.56 vs. 1.97 years, $P < .04$).

This has been seen in other studies that have shown some benefit in watching children with even higher grades of reflux. In a retrospective study of 62 children reviewed after 10 years of follow-up, the overall resolution rate for infants older and younger than 1 year of age was 39% for renal units (Wildbrett et al., 2013). When dichotomizing the patients into low- and high-grade reflux per renal unit in children younger than 1 year of age, mild-moderate reflux grades I to III had a resolution rate of 40% (12/30 renal units) compared with 36% (5/14) with high-grade IV to V reflux. In children older than 1 year of age, resolution rates were different between the groups. The resolution rate was 39% (9/23) and 0% (0/2) for low-grade I to III and high-grade IV to V reflux, respectively. Although the number of patients in the high-grade group older than 1 year of age is small, this study showed that even for children with high-grade reflux, when diagnosed early on, there is spontaneous resolution in over one-third of patients, and this should at least warrant consideration for primary conservative therapy. This might not be the case for children diagnosed with high-grade reflux at an older age.

There was a similar finding in a prospective study of 115 infants with high-grade reflux defined as grade III to IV. A spontaneous resolution rate, to grades 0 to II, was seen in 29% of children in the first year (Sjöström et al., 2004). This decreased to 9% yearly thereafter (Sjöström et al., 2004). In another Swedish study, a spontaneous resolution rate, again defined as reflux grade 0 to II, in a prospectively followed cohort of 77 infants randomized to either endoscopic treatment or CAP showed a spontaneous resolution rate of 21% in the patients on CAP (Nordenström et al., 2017b).

The traditional period of observation for resolution is 5 years. In the study by McLorie et al., 92% of resolved grade III reflux occurred within 4 years (McLorie et al., 1990). A similar finding in another large retrospective cohort of 334 children reviewed over a 12-year period was seen with an annual spontaneous resolution rate for grades I, II, III, IV and V of 45%, 22.7%, 17%, 14.9%, and 9.3%, respectively (Cha and Lee, 2016). At the end of this study, the

Kaplan-Meier curves showed an unusually high rate of spontaneous resolution, with a cumulative resolution rate over a 5-year period for grades I, II, III, IV, and V of 92.9%, 94.9%, 85%, 74.4%, and 64.4%, respectively (Cha and Lee, 2016).

There are significant differences in spontaneous resolution rates across several studies with regard to time to resolution and overall resolution rates for respective grades, which highlights the difficulty and feasibility in capturing the impact of all measurable and nonmeasurable variables that alter the likelihood of reflux resolving over time without significant intervention. **Expectations for reflux resolution and impact of comorbidities depends on a multitude of variables, which define each child's dynamic risk that varies over time.**

Principles of Management

Regardless of era, throughout the history of VUR diagnosis and management, **one principle supplants all: that the preservation of renal function and prevention of UTI and renal scarring is paramount.**

In the face of the paradigm shift after the 2011 AAP recommendation to limit the initial investigation to RBUS (Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management and Roberts, 2011) and ultimate reduction in cystography and associated diagnosis of VUR (Lee et al., 2017), clinical practices have evolved to refocus management into a risk-based fashion. This upholds the notion that VUR cannot be distilled into a dichotomous process. Patients present with a wider spectrum of severity, which extends beyond the classic grading system, including a multitude of dynamic factors, which can alter a child's overall risk for infection or progression over time. For example the perceived impact of associated BBD on resolution of VUR and recurrent UTIs is significant (Peters et al., 2010; Elder and Diaz, 2013; Santos et al., 2017; Shaikh et al., 2016a). Taken together with the fact that the medical and surgical therapies for reflux have historically purported to offer similar benefit to patients, much debate between fundamental approaches to diagnosis, management, and follow-up strategies has existed for decades. The tension embedded in decision making for reflux management stems from the almost perfect results attainable by open surgical correction of reflux, now commonly successful in more than 98% (Baek and Kim, 2013) of cases and in the era of robotic-assisted laparoscopic surgery, likely less morbid (Baek and Koh, 2017).

Regardless, traditional practice in reflux management has held that the end does not justify the means; reflux correction is not indicated merely because it can be corrected easily and reliably. As stated earlier, almost as much as 90% of grade I to II and between 50% to 85% of grade III VUR will resolve (Cha and Lee, 2016; Wildbrett et al., 2013; Knudson et al., 2007; Estrada et al., 2009a; Peters et al., 2010). Even high-grade reflux may resolve spontaneously in certain situations (Alsaywid et al., 2010; Sjöström et al., 2004; Nordenström et al., 2017a, 2017b; Holmdahl et al., 2010; Wildbrett et al., 2013; Farhat et al., 2000).

The essential tenets of reflux management are as follows:

1. Spontaneous resolution of reflux is very common and facilitated by correction of BBD.
2. Higher grades of reflux are less likely to resolve spontaneously, especially when diagnosed in older children after UTI.
3. Sterile reflux is unlikely to cause significant renal damage.
4. Prevention of UTI is more important than VUR resolution.
5. The use of prophylactic antibiotics is safe and beneficial, particularly in high-risk patients.
6. There is a role for medical management for most forms of reflux.

Rather than providing strict guidelines for treatment, these principles provide ample room to individualize treatment on the basis of the particular preferences and tolerances of physicians, families, and patients for the various burdens each of these principles entails. **The classic approach has been to offer daily low-dose prophylactic antibiotic suppression of infections as the first line of treatment while awaiting spontaneous reflux resolution, regardless of grade.** Clearly, age at presentation and grade will factor into predicting when and if resolution is likely to occur. In addition, in patients diagnosed after one or more episodes of pyelonephritis, the presence of scarring on renal scans may temper a decision for extended prophylaxis and observation, particularly if scarring is extensive, the reflux is high grade, renal function is already globally depressed, or congenital dysplasia of one or both kidneys is present. In such cases, tolerance for another infection despite prophylaxis may be low, or simple uneasiness with the notion of ongoing reflux may invite strong consideration for reflux correction.

Some practitioners are withdrawing prophylaxis as the child progresses beyond the toilet-training years, or even after certain risk factors such as BBD have been eliminated. Most children with asymptomatic reflux will require little or no formal follow-up as long as lifelong attention to good bladder and bowel habits is reinforced and they are counseled to seek prompt medical attention and reassessment if pyelonephritis were to occur in the future. Nevertheless, controversy remains as to whether to correct asymptomatic bilateral high-grade reflux with normal RBUS in an older child, especially males. Girls have traditionally undergone surgical correction, even for asymptomatic reflux that fails to resolve after the toilet-training years on the premise that it will reduce maternal and fetal morbidity during a future pregnancy (Mansfield et al., 1995; Hollowell, 2008; Roihuvuo-Leskinen et al., 2015). Using the rationale of antibiotic withdrawal in the older child, several studies have attempted to identify a risk profile for patients that remained infection free off antibiotic prophylaxis and consequently, those that would be at higher risk for infection off antibiotic prophylaxis (Baquerizo and Peters, 2014; Drzewiecki et al., 2012; Cooper et al., 2000). Two studies showed that between 8% and 10% of patients will subsequently develop recurrent febrile UTIs (Drzewiecki et al., 2012; Cooper et al., 2000; Leslie et al., 2010), mandating re-evaluation and possible surgical correction of reflux (Cooper et al., 2000). In cases in which the cessation of antibiotics is desired, it is incumbent on the clinician to identify *prospectively* if the child demonstrates a sufficiently reduced risk (e.g., resolved BBD) to ensure that cessation of antibiotics does not lead to recurrent infection (Hidas et al., 2015).

Medical Management: Continuous Antibiotic Prophylaxis

Although some reports have suggested the existence of “waterhammer” renal damage from high-grade reflux of sterile urine against the renal papillae (Hodson et al., 1975), no such clinical entity has been predictably demonstrated. Because it is not reflux per se that is actually being managed, **the hallmark of observational therapy attempts to decrease certain risk factors to prevent infection and maintain urinary sterility through the judicious use of single daily low-dose CAP.** Often, antibiotics are given as oral suspensions once per day and preferably at night. **Nighttime dosing allows for antibiotic concentration in the bladder urine over the longest period of expected physiologic retention, when infection is most likely to develop.** For children younger than 2 months of age, the most commonly used medications are trimethoprim and amoxicillin. Antimicrobials in children over this age are numerous, and practice patterns vary from region to region. Clinicians should consult local susceptibility tables and initiate optimal antimicrobial therapy. See Table 29.6 for a list of commonly used prophylactic antibiotics and their doses.

TABLE 29.6

Commonly Used Prophylactic Antibiotics and Their Dosages

ANTIBACTERIAL AGENT	DOSAGE	CAUTION IN AGE GROUP	ADVERSE EFFECTS[a]
Amoxicillin	5 mg/kg/day	None	Diarrhea
Sulfisoxazole (sulfafurazole)	20–30 mg/kg/day	<2 months	Kernicterus
Trimethoprim	2 mg/kg/day	<3 months	Hyponatremia
Trimethoprim/sulfamethoxazole (cotrimoxazole)	Trimethoprim 1–2 mg/kg/day 1–2 mg/kg/day	<2 months	Kernicterus
Nitrofurantoin	2–3 mg/kg/day	<1 months	Hemolysis in G6PD deficiency
Cefalexin		None	

[a] The most important adverse effect for each treatment is listed.

G6PD, Glucose-6-phosphate dehydrogenase.

Data from Shah G, Upadhyay J. Controversies in the diagnosis and management of urinary tract infections in children. *Paediatr Drugs.* 2005;7(6):339–346.

Children younger than 2 months of age possess relative hepatic immaturity and are unable to clear sulfamethoxazole efficiently; the drug displaces fetal bilirubin and leads to jaundice. After 2 months of age, the antibiotic of choice becomes trimethoprim-sulfamethoxazole (TMP-SMX; Septra, Bactrim). Like virtually any drug, some mild side effects should be kept in mind and include gastrointestinal upset and allergy. Although transient leukopenia has been reported with TMP-SMX, it is rare, resolves with discontinuation of the drug, and is not believed to be significant enough to warrant regular monitoring of white blood cell counts in all children taking the drug. The other drug most commonly used is nitrofurantoin (Macrodantin). Nitrofurantoin may minimize the development of resistance to fecal organisms, the latter being the largest reservoir for urine infectivity. This drug can uncommonly produce interstitial lung disease (pulmonary fibrosis and interstitial pneumonitis). However, oral tolerance is less than with TMP-SMX because of taste, and gastrointestinal symptoms are subjectively worse. A comprehensive literature review of the use of these drugs by Karpman and Kurzrock in children revealed a low incidence of significant hepatic (five patients) or pulmonary (nine patients) involvement, almost always associated with full-dose rather than once-daily low-dose therapy (Karpman and Kurzrock, 2004). Finally, a growing literature on the use of probiotics (live microorganisms such as strains of *Lactobacillus*, which may displace and suppress the growth of uropathogenic bacteria) is addressing UTI prophylaxis in children (Bruce et al., 2003; Reid and Devillard. 2004; Salvini et al., 2004). The mechanisms that underlie the demonstrated benefit of probiotic use are now emerging (Reid and Bruce 2006; Storm et al., 2011). Further studies will be required to define the use of this attractive approach in the medical treatment of patients with reflux.

Breakthrough febrile UTIs or pyelonephritis while on antibiotic prophylaxis, despite appropriate bladder and bowel habits, are generally considered an indication for termination of medical management with CAP and correcting the reflux. This possibility underscores the importance of proper antibiotic selection and dosing, patient and parental acceptance and compliance with the chosen therapy, and meticulous attention to proper collection and handling of urine culture specimens. **Although the interaction between host defenses and bacterial virulence factors is what dictates BUTI, Smellie has provided useful interpretations surrounding practical causes of BUTI: (1) If the organism is sensitive to the prescribed prophylactic antibiotic, the child or parent has likely not been compliant or the dose is too low. (2) If the organism is resistant to the prescribed antibiotic, either the residual bladder volume is too high too often or the dose is too high** (Smellie, 1991). Indeed, many referrals for definitive reflux correction result from BUTI after full-dose antibiotic usage for extended periods. However, currently CAP is selectively discontinued in patients with low risk for UTI, demonstrating that persistent reflux per se may never be the cause of morbidity. Thus factors associated with reflux resolution should not be conflated with the more important factors that may be associated with its complications. Hidas et al. retrospectively developed a risk-based model from factors identified to be associated with BUTIs. Using these factors, they prospectively validated the model in another cohort of patients and confirmed that there was little difference between what the model predicted and actual 2-year BUTI rates, which were 19% and 21%, respectively. The patients were stratified into three risk groups based on parameters in the risk model and showed that the 2-year risk for BUTI for children on prophylactic antibiotics was 8.6%, 26.0%, and 62.5% for low, intermediate, and high risk-groups, respectively (Hidas et al., 2015).

Additionally, several risk calculators have been devised that incorporate current, known modifiers of risk profile (Baquerizo and Peters, 2014). Some of these factors include grade and laterality of reflux, age of child, presence of BBD, number of infections, presenting symptoms, bladder volume at time or reflux, associated anomalies, and presence of renal scarring (Baquerizo and Peters, 2014; Cooper, 2012).

Antibiotic Controversies and Potential New Approaches

Summarizing what has been learned from the retrospective and prospective studies discussed thus far helps achieve a broader appreciation for reflux management. Several key points are summarized as follows:

1. Antibiotic prophylaxis appears to provide little benefit for those with grade II or lower VUR, particularly in the absence of BBD (Wang et al., 2018; Garcia-Roig et al., 2018; Roussey-Kesler et al., 2008).
2. Conversely, antibiotic prophylaxis does appear to be beneficial for those with grade III or higher VUR, at least among girls (Holmdahl et al., 2010).
3. Approximately 15% of children with VUR will have a recurrent febrile UTI within 2 years, and about 15% of these children will develop a renal scar (Shaikh et al., 2010).
4. Bowel and/or bladder dysfunction is a major risk factor for recurrent UTIs on or off antibiotics, which will occur in about 45% of children with BBD, as opposed to 15% of those without BBD (Peters et al., 2010).
5. A higher grade of VUR is associated with an increased risk for both pyelonephritis and new renal damage (Alsaywid et al., 2010).
6. The effect of age on the risk for renal damage is not well defined, although many believe that younger children are more susceptible to renal damage from pyelonephritis.

With this in mind, the principal rationale for antibiotic use in the management of reflux is the prevention of UTI, principally febrile pyelonephritis, which may lead to permanent postinfection renal scarring. Driving this rationale in part is the belief that the *first* febrile UTI, in the presence of reflux, will create the greater proportion of clinically significant postinfection scarring, despite the fact that this concern is based on animal models of experimentally induced reflux with a priori **normal** renal development (Torres et al., 1985).

However, several prospective studies have brought into question the ability of chronic low-dose antibiotic prophylaxis to prevent UTI in children with and without reflux and even in children with significant high-grade VUR to prevent significant renal damage (Garin et al., 2006; Roussey-Kesler et al., 2008; Pennesi et al., 2008). For example, in children with grade II to IV VUR, after an initial UTI, randomization of 50 patients each to antibiotic prophylaxis versus no-treatment groups showed no difference in the rate of subsequent UTI or renal scarring (Pennesi et al., 2008). This was also seen in the multicenter French trial of 225 children with reflux 1 to 3 years of age, randomized to CAP versus no treatment. Although this found a difference in the rates of UTI between groups, no statistically significant reduction overall was seen, although a subset analysis did suggest some benefit in boys with grade III reflux (Roussey-Kesler et al., 2008). As a corollary, patients with ongoing reflux in whom prophylactic antibiotics have been withdrawn have not suffered any increased incidence of UTI when compared with age-matched refluxing control patients who remain on prophylaxis (Leslie et al., 2009; Baquerizo and Peters, 2014; Drzewiecki et al., 2012). Similarly, patients who have failed endoscopic reflux correction that remains uncorrected fail to show any increased incidence of UTI regardless of whether they remain on prophylaxis (Moore et al., 2009).

Initial studies were plagued with a host of important shortcomings, including small patient numbers, heterogeneous patient populations, high dropout rates, inaccurate urine-collection methods (i.e., bags), no placebo controls, routine screening rather than evaluation in response to clinically significant events, screening bagged sample collections in uncircumcised infants, and lack of distinction between febrile and nonfebrile UTIs. Several prospective studies have attempted to address many of these shortcomings.

Nevertheless, despite their limitations, these studies have succeeded in shedding light on an evolving approach to managing VUR in which it is no longer considered a dichotomous condition, but indeed a dynamic process. It is influenced by a host of environmental and innate patient variables, which if not accounted for, lead to a reduction in treatment success.

This was abundantly clear in the Swedish Reflux Trial in which even in high-grade VUR, unless one accounts for gender differences, associated BBD, and age of the patients, expectations for benefit of a particular therapy cannot be realistically achieved (Brandström et al., 2010c). It offered a plausible alternative to up-front correction with minimally invasive approaches for even high-grade disease.

When added to the underlying concern for the long-term use of antibiotics in general, studies that bring into question the efficacy of antibiotic prophylaxis are giving rise to reflux management alternatives. These include focusing more on modifiable factors such as BBD and using CAP as a tool to decrease a child's overall risk, until other modifiable factors, such as BBD, can be corrected.

Many studies have called into question, at least for low-grade VUR, mostly grades I and II and select grade III, that one alternative is close observation for UTI symptoms without CAP, coupled with early and precise treatment of culture-proven UTI. Two pediatric studies of children with UTIs suggest that early (within 24 hours) versus later (within 4 to 7 days) antibiotic treatment does not necessarily reduce the incidence of postpyelonephritic scarring if the kidneys become involved in the UTI, though early treatment may reduce initial renal involvement (Doganis et al., 2007; Hewitt et al., 2008). Moreover, in both studies, reflux was not found to be a significant variable affecting scarring incidence, and results should be interpreted with caution. Limitations such as precise knowledge of timing of UTI onset and the previously mentioned limitations of DMSA scanning in differentiating preexisting renal dysplasia from true postinfection renal scars remain.

Finally, given the uncertain incidence of incidental and clinically silent VUR in the normal population and the high propensity for reflux to resolve over time, primary treatments, such as endoscopic correction or open surgical repair, without knowing which patients will benefit physiologically and clinically, will likely result in both unnecessary correction of reflux destined to resolve naturally and/or correction of reflux with no clinical benefit. This brings home the notion that any treatment, either pharmacologic, surgical, or through close observation, requires the clinician to understand his or her patient beyond the mere presence of VUR and must include the concept of clinical risk stratification and individualized treatments.

The seminal message for diagnosing and treating children with VUR is becoming clearer, although not yet wholly understood. Approaches to identifying the child's current risk profile, including the host of social and behavioral elements that can affect his or her risk for recurrence of UTI and alter the trajectory to spontaneous resolution, are critical. Teaching and periodic review of perineal hygiene techniques, timely bladder-emptying habits, healthy dietary and bowel measures to prevent constipation, and carefully evaluating family compliance and access to prompt care should influence treatment plans. Patients identified as high risk benefit from initiation of CAP. Given that most VUR has a chance to resolve over time, trying to shift patients into a lower-risk category with CAP until the sum total of the momentum for recurrent infection is diminished is a worthwhile endeavor. This necessitates regular evaluation of patients for known risk variables and attacking each in turn. Movement from risk strata up or down should be considered at each visit based on a child's initial risk at diagnosis, and recommendations move fluidly to mirror that of the patient.

Careful discussion of the obligations and expectations should take place to assess whether watchful waiting is an optimal approach in each case, and careful discernment by the clinician is imperative to be able to predict who benefits from a less invasive approach to VUR therapy.

Landmark Studies

Several studies have attempted to shed light on the efficacy of medical management for VUR as a whole, and looking at patients with specific grades of reflux, namely low-grade VUR, usually defined as grades I to III and high-grade VUR, IV to V. Despite efforts to ultimately clarify the role of CAP in VUR, several well-constructed studies have failed to present a unifying construct that clearly fits the role for medical management. Initially, Edwards et al. led a series of studies that repeatedly demonstrated the ability of low-dose prophylactic antibiotics to prevent infection and renal scarring while reflux resolved in a significant majority of children (Edwards et al., 1977). Since then, several large-scale prospective studies validated this approach in part, however, several questions arose as a consequence. We hope to more fully rationalize the finding in the studies listed in the following sections and help to further define the role for medical management on the natural history of VUR.

International Reflux Study in Children

The International Reflux Study in Children was a North American (Weiss et al., 1992b) and European (Tamminen-Mobius et al., 1992) cooperative study that randomized children younger than 9 years of age with high-grade reflux to CAP or corrective open surgery. **Although surgery was complicated by temporary**

postoperative obstruction in some patients, it was more effective than prophylaxis in reducing, but not eliminating, the occurrence of pyelonephritis. Nevertheless, the incidence of UTI (38%) was the same in both arms. Furthermore, the modalities were equally effective in reducing, but not eliminating, new scar formation. Only the European arm stratified data for the effect of dysfunctional voiding behaviors (18%) (van Gool et al., 1992). **When untreated, voiding dysfunction was associated with more UTIs, more persistent cases of reflux, and greater grade variation during follow-up.**

Birmingham Reflux Study (Birmingham Reflux Study Group 1987)

Medical and surgical management was prospectively compared in a randomized cohort of 104 patients with high-grade reflux over a 5-year period (Birmingham Reflux Study Group, 1987). Again, the incidence of new scars was the same using either treatment modality. Although more than one-half of the patients continued to reflux at 5 years, all cases of new scarring occurred within the first 2 years, consistent with the “big bang” concept of postinfectious renal injury mentioned earlier.

Swedish Reflux Study

This large, prospective trial evaluated prophylaxis and endoscopic injection for children with dilating VUR compared with surveillance across 23 centers in Sweden. Several studies were published regarding UTI recurrence, VUR outcomes, new renal damage, and impact of BBD. There were 203 children (128 girls and 75 boys), 1 to 2 years of age, with VUR grade III or IV randomized to CAP (69), up-front corrective surgery with endoscopic injection (66), or surveillance (68) (Brandströmet al., 2010a). Patients underwent VCUG and renal scintigraphy at entry, and at the end of the 2-year study. Among patients, 67 febrile UTIs occurred in 42 girls, and 8 infections occurred in 7 boys. In girls, the recurrence rate was 19% with prophylaxis, 23% with endoscopic treatment, and 57% with surveillance ($p = 0.0002$). In boys, there was no difference between treatment groups (Holmdahl et al., 2010; Brandström et al., 2010b). When evaluating the presence of new damage, of the 13 girls with new scars, 8 had been on surveillance and 5 had endoscopic treatment, with none seen in the patients on CAP ($p = 0.016$) (Brandströmet al., 2010c). Among boys, two had new lesions. Finally, patients with BBD at follow-up had less resolution of VUR

(Sillén et al., 2010). These studies show that there is a role for up-front treatment with either endoscopic injections or CAP, predominantly in girls, with associated reductions in both recurrent UTIs and new renal scars. Reiterated in an editorial by Canning, gone are the days of treating all patients with VUR similarly, and the importance of identifying at-risk populations is vital (Canning, 2012). Even in high-grade VUR, in this study, we see significant gender differences that call into question traditional dogma.

Randomized Intervention for the Management of Vesicoureteral Reflux Study

The lack of appropriate (placebo) controls or observational arms in prior retrospective reflux studies has further called their conclusions into question. The RIVUR study was sponsored by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) and is a multicenter, double-blind, randomized, placebo-controlled trial designed to evaluate the effectiveness of antimicrobial prophylaxis in children found to have reflux after an initial UTI (RIVUR Trial Investigators et al., 2014). The 19 clinical sites and collaborating centers enrolled 607 children with grade I to IV reflux after an initial or second febrile or symptomatic UTI. Study participants were randomized to oral placebo versus oral TMP-SMX antibiotic prophylaxis. The primary outcome measure was the development of recurrent febrile or symptomatic UTI (Chesney et al., 2008; Greenfield et al., 2008; Keren et al., 2008; RIVUR Trial Investigators et al., 2014). Results suggested that antibiotic prophylaxis reduced recurrent UTI risk by 50%, from 23.6% (72/305) for subjects on placebo to 12.9% (39/302) for those in the prophylaxis arm. The effect was more robust in subjects with febrile UTI or bowel/bladder dysfunction at baseline. However, renal scarring appeared unaffected by prophylaxis (11.9%) versus placebo (10.2%). Despite the robust design of this study and its prospective nature, several limitations highlight the significant challenges in conducting such studies. The compliance figures showed that approximately 75% of antibiotic subjects took the drug only 75% of the time, almost one-third discontinued the drug and were withdrawn from analysis, and 2% in each group reported adverse drug reaction. Using more stringent criteria for treatment failure (e.g., multiple UTI recurrences, ± fever, ± symptoms), twice as many placebo subjects suffered treatment failure (9.5% vs. 5% of antibiotic subjects). However, the converse is that 90% treatment success was achieved with placebo alone. Finally, 484 (83%) of baseline nuclear scans in both groups were obtained 1 to 4 months after the index infection event.

However, the scan data cannot conclude whether positive baseline scan findings were a result of the index infection or were related to renal dysplasia coincident with the genesis of reflux itself.

Since the RIVUR data have been released, several reanalyses have attempted to further shed light on several aspects of this study that contradicted previous literature. As previously discussed, known VUR with frequent infections leads to more renal scarring. Several key studies have also shown benefit to CAP for reduction of UTI. With this in mind, how can one rationalize the findings that there was no difference in renal scarring in the groups, despite seeing the 50% relative risk reduction to CAP? To help provide clarity, Wang et al. reanalyzed the original RIVUR data set and stratified patients into low- and high-risk groups based on known modifiers (Wang et al., 2018). One interesting finding regarding patient population characteristics was that most of the patients were females (>90%) with low to intermediate grade VUR (I to III). Only 8.3% of the overall cohort had grade IV VUR. To reconcile previous findings where there was significant benefit with treating higher-risk patients (Alsaywid et al., 2010; McLorie et al., 1990; Nordenström, Holmdahl, et al., 2017a; Holmdahl et al., 2010), it may be quite plausible that the effects of CAP seen in the RIVUR trial may have been diluted in a predominantly low-risk cohort. There was a greater difference in the number of recurrent UTIs in the low- and high-risk patients, 31.5% versus 11.4%, respectively. The number needed to treat to prevent one infection for low- and high-risk patients was 18 and 5, respectively, providing a more favorable treatment profile. In keeping with previous studies in which there was no significant difference for patients with lower grades of VUR (Roussey-Kesler et al., 2008), Wang's reanalysis confirmed the benefit of CAP in high-risk patients and questioned its value in low-risk patients where the rate of UTI in CAP or placebo was 13.8% and 19.2%, respectively ($p = 0.151$). Although this was an exploratory analysis of a large data set with inherent limitations itself, it attempts to reconcile the findings of separate published work involving low- and high-risk patients (Holmdahl et al., 2010; Roussey-Kesler et al., 2008; Garin et al., 2006) and further reinforces the need for a risk-stratified approach to the management of VUR, with greater attention to patient selection to identify the specific subset of children who stand to benefit clinically from prophylaxis.

Additional Prospective Studies

Medical management alone was assessed in 59 patients (84 refluxing ureters, grades I to III) by the Southwest Pediatric Nephrology Group (Arant, 1992).

Resolution occurred in 67%, BUTI in 33%, and new scarring in 10% of the low-grade and 28% of the patients with grade III reflux. Scholtmeijer demonstrated resolution in 57% of 47 cases of grade III to IV reflux followed by watchful waiting and prophylaxis for 5 years (Scholtmeijer, 1993). Interestingly, 15 cases underwent surgical correction after BUTI, and 6 of these subsequently developed new scars, whereas 2 of the patients managed medically developed new scars.

In the Antibiotic Prophylaxis and Recurrent Urinary Tract Infection in Children (PRIVENT) study, 576 children with a history of UTI were randomized to CAP or placebo (Craig et al., 2009). The patient population was heterogeneous with regard to VUR status and type of follow-up imaging. There was a decrease in the number of UTIs when placed on a low-dose, long-term regime with an absolute risk reduction of 6% from 19% to 13%. The modest decrease was present across all subgroups analyzed. In a similar study by Garin et al., 218 patients with and without VUR were treated with CAP or observation (Garin et al., 2006). After 1 year, there was no statistically significant difference between patients on CAP or in the observations group. The overall incidence of UTI after pyelonephritis in the whole cohort was 20.1%. Among patients in the observation arm, the incidence of infection in patients with and without VUR was 22.4% and 23.3%, respectively ($p = 0.99$). Among patients on CAP, the recurrence rate of UTI after pyelonephritis for those with and without VUR was 23.5% and 8.8%, respectively ($P = 0.63$). This cohort of patients would most closely represent a low-risk group, with only 37 patients overall having at most grade III reflux out of the entire population. In the study by Roussey-Kesler, 225 patients with low-grade VUR I to III were randomized to CAP or no treatment. They found no significant difference in recurrent UTI rates between the two groups: 17% and 26% ($p = 0.2$) for patients on CAP and no treatment, respectively (Roussey-Kesler et al., 2008).

Key Points: Natural History and Management

- Reflux has a natural tendency to resolve spontaneously given enough time.
- The likelihood of resolution is inversely proportional to grade but is influenced by several factors.
- Maintaining urine sterility (through both prophylactic antibiotics and strict attention to bladder and bowel management) is the cornerstone of watchful

waiting medical management.

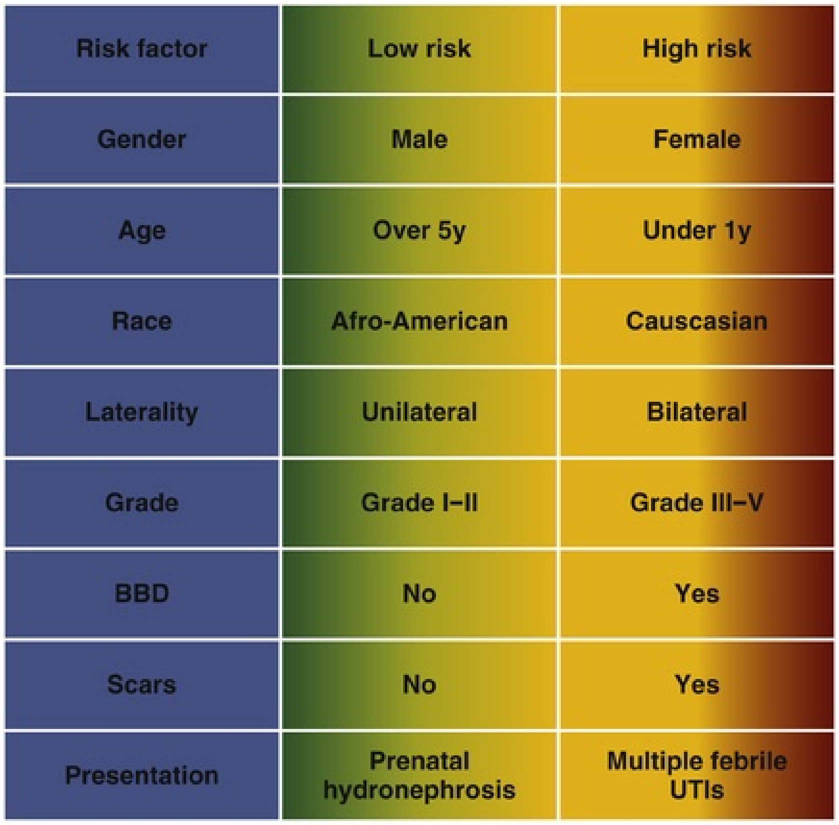
- CAP results in a reduction in UTIs but does not necessarily reduce renal scarring or chronic kidney disease.
- Prophylactic antibiotics are more likely to benefit patients with higher-grade VUR, baseline bladder dysfunction, febrile UTI, BBD, or those that present with a febrile UTI.

Individualizing Patient Care

Throughout this section, several overriding themes have been reinforced; namely the need for individualized care and the importance of reassessing ongoing management and tailoring it to the dynamic changes that either increase or decrease a child's risk for infection.

When a child initially presents to a clinician for care, it is imperative to **establish the severity of the condition and the child's risk for recurrent UTI and renal injury**, which should dictate management. The minimum initial approach necessitates an accurate history to document the number and severity of clinically significant UTIs and to review the upper tracts with a high-quality renal, bladder ultrasound scan to first gauge the extent of renal injury, if any. Once this basic information is obtained, the role for further workup with a VCUG can be considered. In patients with multiple, well-documented, clinically significant UTIs on history, especially with significant associated morbidity, such as need for hospital admission or upper tract findings on ultrasonography, ruling out VUR in the presence of these infections becomes imperative. This contrasts with the patient who presents with an equal number of nonfebrile "infections" with questionable urine studies and a normal ultrasound scan. A clinician may opt to offer a more conservative approach to the workup and management, with likely little adverse outcome.

Our group has developed a tool to help stratify patients at each encounter and assess the likelihood of BUTIs (Hidas et al., 2013) (Fig. 29.19). This same principle was used to retrospectively review 252 patients and identify the dominant candidate risk factors that increase the risk for UTI and then confirmed this risk model in 52 children followed prospectively for at least 2 years (Hidas et al., 2015). What was garnered from this study was that those children at greatest risk for BUTIs were those that presented initially with UTI, had high-grade VUR, were female, and had BBD. Patients were stratified into low-, intermediate-, and high-risk groups based on these variables, thus tailoring management for each child, while providing guidance to the individualized approach to each child's care. In this study, 68% of children with VUR were in the low-risk category and only had an 8.6% chance of BUTI, and 28% were intermediate risk and had a 27% chance of BUTI (Hidas et al., 2015). Only 6.3% were defined as high risk; however their rate of BUTI was 63%. This is consistent with high-quality data that confirms the predominance of low-risk type patients in large cohort studies, when all-comers with VUR are included in the analysis, as is the case in the RIVUR study (RIVUR Trial Investigators et al., 2014; Wang et al., 2018).



Risk factor	Low risk	High risk
Gender	Male	Female
Age	Over 5y	Under 1y
Race	Afro-American	Causcasian
Laterality	Unilateral	Bilateral
Grade	Grade I–II	Grade III–V
BBD	No	Yes
Scars	No	Yes
Presentation	Prenatal hydronephrosis	Multiple febrile UTIs

FIG. 29.19 Risk factors and risk groups for vesicoureteral reflux. (Modified from Hidas G, Nam A, Soltani T, et al. Primary vesico-ureteric reflux: The need for individualised risk stratification. *Arab J Urol.* 2013;11[1]:8–12.)

A clinician can use this risk characterization to better understand the specific child's risk for infection in the context of VUR and guide each patient's care, identifying which factors need to be modified to reduce each child's risk profile, not only to prevent infection, but also to decrease the intensity of treatment and follow-up when possible. As an example: An uncircumcised male child evaluated and found to have BBD and intermediate grade VUR puts him at intermediate risk for BUTI. The clinician may opt to continue or start CAP until the BBD and potential phimosis is confidently treated, at which point the child's risk might be considered to have been downgraded and the risk for BUTI is sufficiently lowered (from 28% to 8.6%) such that CAP can be safely discontinued. Conversely, if a child presents with high-grade VUR, BBD, and is a female, the clinician may consider a trial of CAP, but given that the risk for BUTI is high, discussion with the family regarding a more aggressive approach with up-front correction of VUR may not be entirely unreasonable.

The spectrum of VUR is continuous and dynamic, and seeing it through this lens is critical. The clinician's aim should be to prevent infection, which has been repeatedly shown to be a game changer. The goal should be to allow for the possibility of spontaneous resolution of VUR over time while preventing UTI-associated scarring in the process.

The modern management of VUR should be specific to each child and malleable enough to adapt to the ongoing changes in each child's particular risk profile.

Bladder Anomalies in Children

Aaron D. Martin MD, MPH, Christopher C. Roth MD

The *International Classification of Diseases* (ICD-10-CM) classifies birth defects as structural or functional anomalies, and the urinary bladder can be affected by entities across this spectrum. Structural anomalies include bladder exstrophy, bladder duplication, bladder agenesis, urachal anomalies, and diverticular disease. Functional bladder anomalies are often secondary to other conditions such as bladder outlet obstruction and neurogenic dysfunction. Some conditions, such as the bladder findings in prune-belly syndrome (PBS), may be structural and functional. Many of these conditions represent common clinical entities for the practicing pediatric urologist and are covered in detail elsewhere in this text. This chapter focuses on less commonly encountered congenital anomalies as well as some of the rare acquired conditions of the bladder that may arise in children. Because many of the congenital conditions are encountered prenatally, we review the relevant embryology as well as normal and abnormal prenatal bladder imaging. The current literature regarding the clinical management of these conditions also is discussed.

Congenital Bladder Anomalies

Embryology of the Urinary Bladder

A clinically relevant understanding of the embryologic development of the bladder and urachus is essential to correctly interpret the prenatal and postnatal findings and to counsel patients and/or their families toward optimal management. **Definitive nephrons within the embryologic kidneys begin urine production around the 10th week of gestation; it is at that time that the first signs of lower urinary tract anomalies may become evident** (Rosenblum et al., 2017). The key developmental milestones leading to the handling of fetal urine are important to review. Between the fourth and sixth weeks of gestation, the urorectal septum divides the endodermal cloaca into a ventral urogenital sinus and a dorsal rectum. The cranial part of the urogenital sinus is continuous with the allantois and develops into the bladder and pelvic urethra. The caudal portion gives rise to the phallic urethra in males and the distal vagina in females. Unlike in males, the entire female urethra is derived from the pelvic part of the urogenital sinus. The allantois develops as an extraembryonic cavity from the yolk sac and connects with the cranioventral portion of the cloaca, the future bladder. Around the fourth to fifth month of gestation, the allantoic duct and ventral cloaca involute as the bladder descends into the pelvis. **The descent causes the allantoic duct to elongate because it does not grow with the embryo. This epithelialized fibromuscular tube continues to become narrower until it obliterates into a thick fibrous cord, the urachus** (Moore et al., 2011). **The obliterated urachus becomes the median umbilical ligament and connects the apex of the bladder with the umbilicus** (Nix et al., 1958).

Normal and Abnormal Antenatal Sonographic Findings of the Bladder

Normal fetal bladder imaging by default is absence of abnormal bladder imaging with varying and broad criteria to suggest an abnormality is present. Normal physiologic variation and bladder cycling require careful attention before diagnosing an abnormality. The fetal bladder manifests as an elliptical structure filled with anechoic fluid within the pelvis. It is bordered laterally by the umbilical arteries. The pubic bones mark the anterior border and the rectosigmoid the posterior border. The bladder wall thickness should not exceed 3 mm, and the mucosa and musculature have an echogenicity similar to that of other structures in the pelvis (McHugo and Whittle, 2001). **The bladder can be visualized in approximately 50% of cases in the fetal pelvis at the 10th week of gestation, concurrent with the onset of urine production** (Green and Hobbins, 1988)**. The detection rate increases with fetal age to 78% at 11 weeks, 88% at 12 weeks, and almost 100% at 13 weeks** (Rosati and Guariglia, 1996)**. Compared with abdominal ultrasound, transvaginal ultrasound increases the quality of the obtained images as well as the detection rate with the bladder visualized in 94% of women at 12 weeks estimated gestational age** (Braithwaite et al., 1996)**. The fetal bladder empties every 15 to 20 minutes; therefore a second ultrasound in the same setting is mandatory in case of nonvisualization of the bladder. The bladder's diameter increases during the first trimester but should not be more than 6 to 8 mm.**

The fetal sex, the amount of amniotic fluid, and the appearance of the umbilical cord become increasingly important in the interpretation and differential diagnosis of abnormal bladder findings. Fetal sex is difficult to determine before week 14 and should not be based on the presence or absence of a phallus but on visualization of the testes (Efrat et al., 1999). The measurement of amniotic fluid as an indicator of fetal urine production is a critical portion of every antenatal ultrasound. Until 16 weeks of gestation, the amniotic fluid is mainly consistent with placental transudate, at which time it changes to predominantly fetal urine (Takeuchi et al., 1994). The umbilical cord should contain two arteries and one vein without evidence of a fluid-filled urachus (Bronshtein et al., 1990).

Nondilated or Absent Bladder

In addition to dilation the fetal bladder may also appear hypoplastic or absent on ultrasound. In cases of nonvisualization of the bladder, it is possible that the bladder is completely absent, malformed, or is not filling with urine. An otherwise normal bladder may not fill with urine secondary to renal dysfunction or ectopic drainage of urine. When the bladder is poorly visualized, specific notation of renal development and amniotic fluid level become important factors in determining the possible cause. **To truly diagnose an absent fetal bladder on ultrasound, the examination has to be repeated after 15 to 20 minutes to**

rule out that the fetus has not simply emptied the bladder.

Bladder Agenesis.

Embryologic development of bladder agenesis remains difficult to explain. The division of the cloaca into the urogenital sinus and the anorectum apparently is regular, because the hindgut is usually normal. Therefore the defect can be due to either atrophy of the cranial part of the urogenital sinus or failure to incorporate the mesonephric ducts and ureters into the trigone (Krull et al., 1988). The absence of the bladder is often associated with neurologic, orthopedic, or other urogenital anomalies, such as renal dysplasia or agenesis or absence of the prostate, seminal vesicles, penis, and vagina (Aragona et al., 1988). **The incidence is approximated at 1 : 600,000 with 65 cases in the literature including 26 live births, a significant majority are female** (Nazer et al., 2018)**. The defect is compatible with life only if the ureters drain ectopically into normally developed müllerian structures in females or in the rectum in males.** In surviving infants, the diagnosis can be confirmed by antegrade or retrograde contrast imaging. MRI and CT imaging can also be used to provide greater anatomic detail before surgical intervention (Indiran et al., 2013). Renal function can be preserved after creation of an ureterosigmoidostomy or external stoma (Berrocal et al., 2002; Glenn, 1959).

Bladder Hypoplasia.

The bladder can be hypoplastic as a result of inadequate filling or storing of urine during fetal life. Although the bladder is formed during fetal development and can be detected on antenatal ultrasound throughout pregnancy, it never reaches an adequate capacity. Conditions caused by inadequate bladder outlet resistance (e.g., severe epispadias), separation defects (e.g., urogenital sinus abnormalities), abnormalities of renal development (e.g., bilateral renal dysplasia or agenesis), or urine bypassing the bladder (e.g., ureteral ectopia) can lead to underdevelopment of the fetal bladder. Some of these bladders grow once the malformation is corrected; however, later bladder augmentation is often required to reach adequate capacity.

Cloacal and Bladder Exstrophy.

Bladder exstrophy conditions are characterized by the presence of a bladder template only. Therefore it can be suspected in the absence of regular bladder filling during fetal ultrasound. **Bladder exstrophy can be distinguished from**

bladder agenesis by the bladder template on the lower abdominal wall, which, along with the amniotic fluid level, remains normal throughout the pregnancy (Gearhart et al., 1995; Mirk et al., 1986). Covered cloacal exstrophy can have a unique presentation when an omphalocele, pelvic diastasis, and genital anomalies are present, although so too is a fluid-filled bladder (Mallmann et al., 2014). Despite a recognizable pattern on prenatal ultrasound, a majority of bladder exstrophy cases are not diagnosed prenatally. Fetal MRI has been used in cases of suspected exstrophy, and this modality has been shown to provide additional anatomic details that could enhance the completeness of prenatal counseling (Goldman et al., 2013).

Dilated Bladder and Congenital Megacystis

Megacystis.

Historically, congenital megacystis was thought to be caused by bladder neck obstruction, leading to massive bilateral vesicoureteral reflux (VUR) and a thin bladder wall (Paquin et al., 1960; Williams, 1957). Even the describing authors recognized that surgical interventions at the bladder neck level did not change the future outcome. Harrow (1967) revisited the subject and recognized that all patients had normal urethras and complete emptying of their bladders on voiding cystourethrography (VCUG). Therefore the observed reflux is not an after-effect of obstruction but rather the cause of the bladder dilation from continuous recycling of the urine between the upper tract and bladder (Harrow, 1967). **Although this scenario is relevant in a subset of children with VUR, the clinical term *megacystis* over time has evolved to not directly reference any one cause of bladder dilation, more so; in the modern literature it simply implies a prenatally dilated bladder.**

Megacystis, much like hydronephrosis, is not a diagnosis but a finding on prenatal ultrasound that requires careful attention to differentiate the physiologic from the pathological. Unlike the kidney, however, the bladder by design will at times be distended with urine, making this finding particularly difficult to qualify. As such, the criteria for diagnosing megacystis have been refined over time. A large retrospective evaluation of more than 24,000 fetuses identified megacystis without an objective definition in 15 (0.06%) fetuses. In the same report, 300 consecutive fetuses between 10 and 14 weeks’ gestation were assessed to evaluate bladder length as a ratio to crown-rump length. All the control study subjects were found to have a sagittal bladder length less than 10%

of crown-rump length, which equated to bladder length of 6 mm or less (Sebire et al., 1996).

With use of the same method of assessment, those previously diagnosed with megacystis were found to have a minimum bladder length to crown-rump length ratio of 13% and a minimum bladder diameter of 8 mm. **Thus at 10 to 14 weeks' gestation the longitudinal bladder length should be 6 mm or less and can be considered abnormal if at least 8 mm** (Sebire et al., 1996)**. Other researchers have used similar definitions of more than 6 mm** (Favre et al., 1999; Pellegrino et al., 2017) **and at least 7 mm** (Kagan et al., 2010; Liao et al., 2003; Robyr et al., 2005) **in their reports on megacystis in the first trimester** (Fig. 30.1).

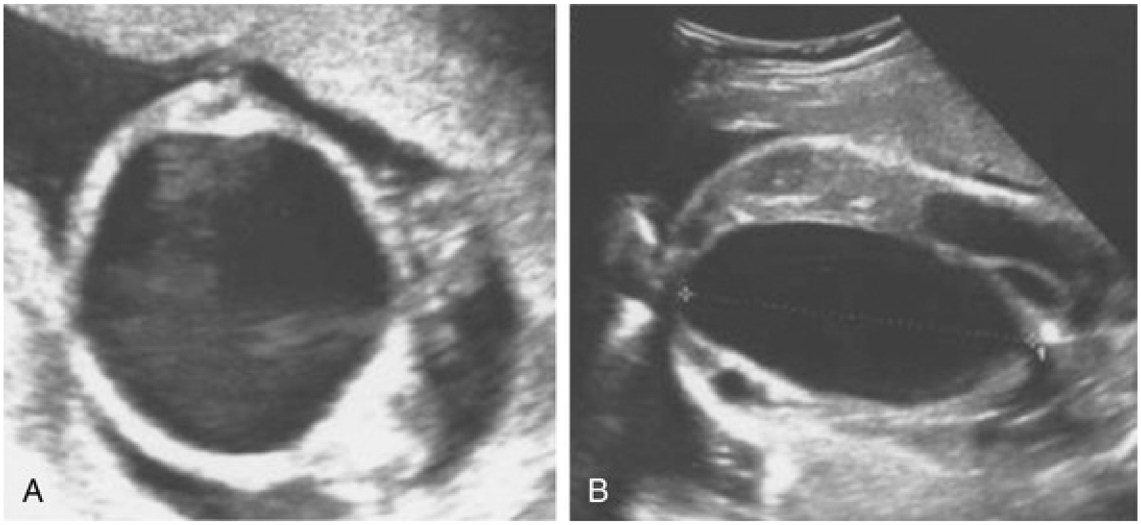

FIG. 30.1 Fetal megacystis at 18 weeks of gestation (A) and at 38 weeks of gestation (B). (From Pellegrino M, et al.: Prenatal detection of megacystis: not always an adverse prognostic factor. Experience in 25 consecutive cases in a tertiary referral center, with complete neonatal outcome and follow-up. *J Pediatr Urol* 13:486.e1–486.e10, 2017.)

Defining an abnormal bladder beyond the first trimester has been less precise, and most reports use a subjective definition. Studies focusing on later gestation tend to narrow in on a disease process such as posterior urethral valves (PUV) (Hutton et al., 1994) and PBS (Chen et al., 2010), in which bladder enlargement becomes a part of a series of findings and is therefore less importantly defined solely by size. Also important beyond the first trimester is the recognition of bladder cycling as a marker of normal function. **An "enlarged bladder" has been referenced in several studies as a bladder that does not empty during a**

45-minute period of sonographic observation. This definition of megacystis is often used beyond the first trimester (Bornes et al., 2013; Müller Brochut et al., 2014; Robyr et al., 2005).

Attempts have been made to objectively define megacystis in the second and third trimesters. Investigators have sought to develop a formula to use in predicting expected bladder sagittal length (SL). Using a series of 39 control fetuses, they observed a near linear relationship between bladder length and gestational age (GA) between 15 and 40 weeks' gestation. Using this data they developed a formula

$$\text{SL (mm)} = \text{GA (weeks)} - 5 \ (95\% \ \text{CI} +/- 7)$$

,which can be applied to fetuses in the referenced age range. A measurement above the 95% CI (i.e., GA + 2) would be considered an "enlarged bladder," although "megacystis" was defined as 10 mm greater than the 95% CI (i.e., GA + 12). The distinction between the two terms is reasoned to allow more specific prenatal counseling (Maizels et al., 2004).

The differential diagnosis for megacystis includes obstructive and nonobstructive processes that can be observed in the fetus and child. Obstructive processes can be grouped under the term lower urinary tract obstruction (LUTO), which can be caused by PUV, urethral atresia, and urethral stenosis/anterior urethral valves. Nonobstructing causes can include PBS, megacystis-microcolon-intestinal-hypoperistalsis syndrome (MMIHS), and cloacal anomalies with recognized crossover for some of these conditions. A meta-analysis of 26 publications reviewed more than 1000 subjects with megacystis and reported on the definitive diagnoses that were made in these reports. **In a majority of patients a diagnosis was made with PUV (57%) being the most common. Urethral atresia/stenosis (7%), PBS (4%), MMIHS (1%), and cloacal anomalies (0.7%) represented the other defined causes. No defined cause could be found in more than one-third of the fetuses (36.5%). Because the male-specific diagnosis of PUV is the leading cause of megacystis, this prenatal finding demonstrates an 8 : 1 male predominance** (Taghavi et al., 2017; Table 30.1).

From Taghavi K, Sharpe C, Stringer MD: Fetal megacystis: a systematic review. *J Pediatr Urol* 13:7–15, 2017.

Megacystis can include a range of bladder measurements and can have an unpredictable outcome based on the data available during the first trimester. This observation has led several researchers to work toward better defining outcomes based on the degree of bladder dilation, gestational age at presentation, and genetic abnormalities. Chromosomal abnormalities in association with megacystis have been reasoned to result in poor outcomes. High rates of termination of pregnancy for fetuses with megacystis and aneuploidy limit an accurate assessment of general urologic outcomes in this population. **An abnormal karyotype has been observed in 30/145 (21%) fetuses with megacystis. The most common abnormalities were trisomy 13 and 18, which accounted for 80% of affected karyotypes. The observed rate of these patterns significantly exceeded the expected rate based on maternal age and fetal nuchal translucency.** Pregnancy termination was elected in 26/30 aneuploid fetuses and the remaining 4 fetuses did not survive to term (Liao et al., 2003).

The authors evaluated the remaining fetuses with normal karyotypes and follow-up data to determine the rate of spontaneous resolution for megacystis. **They compared fetuses with longitudinal bladder diameters of 7 to 15 mm with those with diameters of more than 15 mm. The spontaneous resolution rate in the former group, which included 79 fetuses, was 89.9% with the remainder being found to have obstructive uropathy. This contrasts sharply with the latter group, which had a 0% resolution rate with all 30 subjects having obstructive uropathy** (Liao et al., 2003).

One of the larger studies regarding resolution of megacystis comes from the collective database shared by the fetal medicine units across the Netherlands (Fontanella et al., 2017). From 2000 to 2014, 541 fetuses were evaluated for megacystis with 247 excluded from further evaluation secondary to termination, fetal intervention, or loss to follow-up. The prenatal assessment of genetic abnormalities was not included in the database, although the high rate of pregnancy termination (35% of the study population) results in a selective group available for evaluation. Early megacystis was defined as bladder enlargement detected before 18 weeks gestational age (WGA) and late megacystis as that detected after 18 WGA. Routine follow-up imaging was used to detect resolution of megacystis. Early presentation (before 18 WGA) and early resolution (before 23 WGA) were key determinants in the study. **The overall rate of resolution**

was 20% with those with early presentation demonstrating 38% resolution and those with late presentation demonstrating 12% resolution. In the subgroup of fetuses with early presentation, a maximal longitudinal bladder diameter of 12 mm or less was a sensitive predictor of resolution with 70% resolving during gestation. Of those presenting before 18 WGA and resolving before 23 WGA, none demonstrated urologic sequelae requiring surgery postnatally. Conversely, 84% of those presenting after 18 WGA and resolving at some point beyond 23 WGA required urologic intervention postnatally despite prenatal resolution of megacystis. This particular study highlights the relevance of prenatally detected bladder enlargement and its later clinical significance.

Megacystis Microcolon Intestinal Hypoperistalsis Syndrome.

MMIHS is a specific cause of a dilated fetal bladder and is a condition not covered elsewhere in this text. Although representing only a small percentage of cases with megacystis (approximately1%), this clinical entity remains important secondary to morbidity of the syndrome. **Prenatally megacystis is the most consistently recognized feature, and unlike cases of LUTO, most of these patients have normal to increased amniotic fluid levels. The gastrointestinal findings of MMIHS are often not evident prenatally on ultrasound, although amniotic fluid sampling for digestive enzymes, if done, will be abnormal in 80% of cases** (Muller et al., 2005). The pathological basis of the disease is smooth muscle dysfunction within the gastrointestinal and urinary systems. Actin smooth muscle filament function has been evaluated genetically with mutations in *ACTG2* identified in this population (Tuzovic et al., 2015).

There is a female predominance with roughly 70% of historic cases. **The overall survival rate based on reported cases is 20%; however, when considering cases from 2004 to 2011 the survival rate improved to 55%, suggesting improvement in understanding and management of this condition** (Gosemann and Puri, 2011). **The postnatal findings include abdominal distention, bilious vomiting, and failure to pass meconium. The clinical suspicion of bowel obstruction in the background of an enlarged bladder should be evaluated as MMIHS.** Differentiation from other causes of intestinal obstruction is based on clinical findings, although colon biopsy confirming the presence of ganglion cells can be done to rule out Hirschsprung disease. Contrast imaging of the intestinal tract often demonstrates hypomobility of the small intestine and a small colon. The enteric complications of this syndrome can be fatal, and these neonates are often managed with ileostomy, gastrostomy tube insertion, and TPN. Complications of TPN including blood-borne infections and liver dysfunction are leading causes of mortality in this population, and small intestinal transplantation has been successfully used with promising results.

The urologic morbidity is often secondary to enteric complications, although short-term management of the bladder with intermittent catheterization or vesicostomy is important for minimizing complications from urinary retention. VUR is uncommon in this syndrome and therefore early contrast imaging of the bladder is of limited utility. **Once these children are stable from an enteric standpoint, more thorough evaluation with urodynamics can be considered with an acontractile bladder the expected finding. Normal micturition in older patients has been reported, although most patients will require ongoing CIC. Like patients with a posterior urethral valve or neurogenic bladder, lifetime urologic care will be needed** (Wymer et al., 2016).

Bladder Duplication

Duplication of the bladder and urethra can be complete or incomplete with variable orientation. Abrahamson (1961) attempted to classify the various bladder duplication anomalies and found complete duplication in the sagittal plane the most common. **In incomplete duplications, the two bladder halves communicate and are usually drained by a single urethra. In complete duplications, the two bladders are fully separated entities with normal mucosa and a full-thickness musculature wall divided by a peritoneal fold** (Fig. 30.2)**. Although the size and quality of each entity can be different, they are usually supplied with their own ureter and are drained by an individual urethra and external meatus** (Esham and Holt, 1980). In rare cases, one bladder can lack a urethra. This leads to ipsilateral renal dysplasia via complete obstruction (Cheng and Maizels, 1996). Continence can vary.

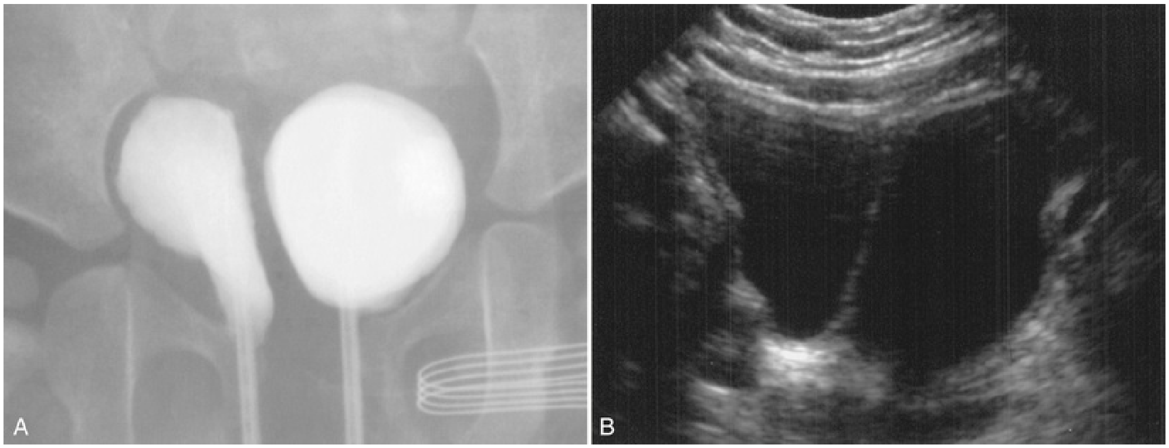

FIG. 30.2 Complete bladder duplication. (A) Vesicoureterogram image of complete bladder duplication with catheters inserted into each individual urethra. Note the size discrepancy. (B) Ultrasound image of the same patient.

Associated duplication anomalies of the external genitalia have been reported in up to 90% of cases; associated duplication anomalies of the lower GI tract have been reported in up to 42% of cases (Kossow and Morales, 1973). Duplicated vaginas can be connected to a separate unicornate uterus. Duplicated penises are supplied with an individual urethra. Additional urologic abnormalities such as VUR, renal ectopia, or dysplasia are commonly found. Association with other nonurologic congenital anomalies are more frequent in sagittal than coronal duplications. Multiple manifestations have been described, including GI malformations, duplications of the spine, spina bifida conditions, and various fistula formation between the urogenital and GI tract (Berrocal et al., 1999). In duplication variations of the classic cloacal-bladder exstrophy complex, patients have an exstrophic bladder and urethra in addition to a closed regular intra-abdominal bladder (Perren and Frey, 1998).

The diagnosis is often made in the newborn period because of associated malformations of the GI tract or external genital tract. However, many children are not diagnosed until recurrent infections or incontinence initiates a urologic workup. Although similarities exist, there are many variations necessitating individual management. Complete preoperative diagnostic evaluations with karyotype, ultrasound, videourodynamic studies, genitogram, and cross-sectional imaging are useful to understand the anatomic relationships. VCUG and nuclear renal scans can supply additional information regarding VUR and renal function. Often the final treatment plan has to be deferred until the time of endoscopic and surgical exploration of the malformation. Initial treatment is directed toward renal preservation and prevention of infections by relieving possibly obstructed genitourinary tracts. Long-term goals include achieving continence and reconstructing the internal and external genitalia. Incomplete duplications may not require surgical procedures if both bladder halves are sufficiently drained by a common urethra. In complete duplications, the two bladders can be combined into one. If both sphincter complexes are competent, the distal urethras are connected. If one is incompetent, the corresponding bladder neck can be closed and the connected urethra excised. Duplicated vaginas are combined in the midline, and a vulvoplasty is performed. The urogenital duplications also can be left uncorrected if the patient is asymptomatic; Gastol reported two successful pregnancies in a 26-year-old woman (Gastol et al., 2000). **Because of the rarity of the disease and the large variety of manifestations, the surgeries must be individualized and should be performed in centers experienced in complex urogenital reconstruction.**

Congenital Diverticula

Diverticula typically develop as herniation of bladder mucosa between defects of bladder smooth muscle fibers. The neck of the resulting diverticulum depends on the size of the muscular defect. The incidence is reported to be low, with 1.7% in a selected pediatric population of children undergoing radiographic evaluation for symptomatic disease (Blane et al., 1994). The true incidence is likely higher as symptomatic diverticula are rare and undiscovered.

Bladder diverticula can be detected on prenatal ultrasound (Gaudet et al., 1999) **but are mostly discovered during postnatal workup for infection, hematuria, incontinence, or obstruction. Large diverticula can be seen with sonography, but the gold standard remains VCUG, which will reveal possible accompanying VUR and likelihood of postvoid retention of urine.** Nuclear renal studies can be used to obtain information concerning anatomy, kidney function, and ureteral obstruction if hydroureteronephrosis is present. Congenital diverticula can be dynamic and may not be present on every study. Radiographic studies may have to be repeated in cases of continuous clinical suspicion.

Paraureteral Congenital Diverticula.

Paraureteral diverticula are by far the most common congenital diverticula and categorized as primary or secondary by Hutch in his landmark article (Hutch, 1961). **Primary paraureteral diverticula are seen in smooth-walled bladders,**

occur isolated with no other diverticula, can be intermittent on imaging, and happen in children with no infravesical obstruction. Secondary paraureteral diverticula are found in trabeculated bladders as one of many diverticula in the bladder, are always present on imaging, and are caused by infravesical obstruction. These are acquired and therefore are discussed later in this chapter.

Primary diverticula arise as a localized herniation of bladder mucosa through the ureteral hiatus between the intravesical ureter and the roof of the ureteral hiatus. These primary diverticula are most likely caused by a congenitally deficient bladder wall (Fig. 30.3). Some authors have implied an isolated defect in the Waldeyer sheet; however, congenital diverticula often occur on one side only and a unilateral defect seems unlikely (Stephens, 1963).

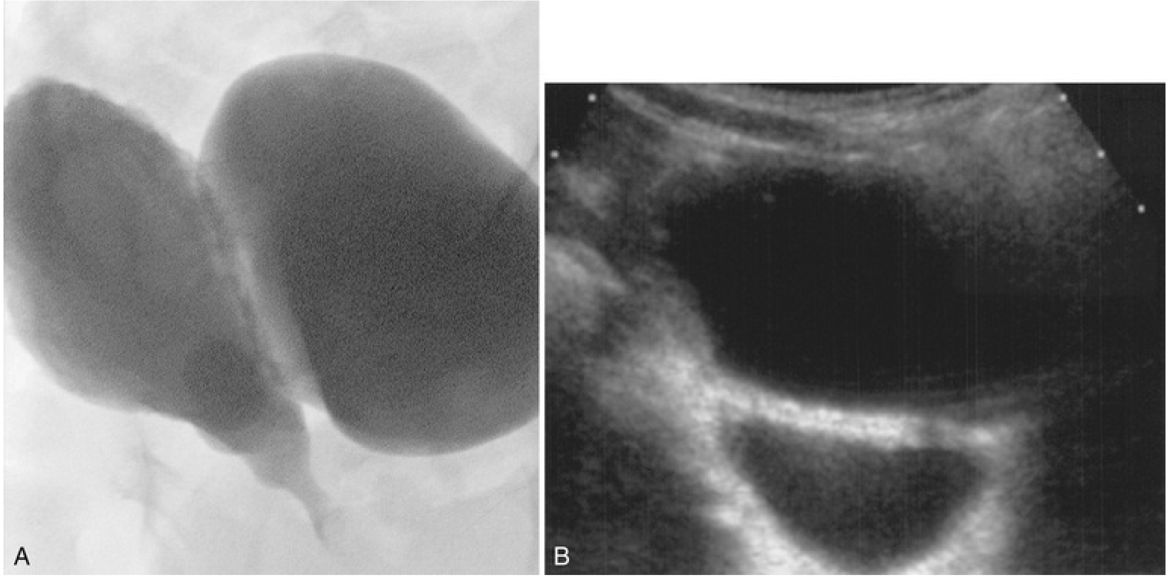

FIG. 30.3 Primary paraureteral diverticulum. (A) Vesicoureterogram image of large primary paraureteral diverticulum. (B) Ultrasound image of the same diverticulum.

Small, asymptomatic congenital diverticula detected during unrelated workups can be treated conservatively. Many surgeons tend to recommend excision of paraureteral diverticula if they are accompanied by VUR. Girls show spontaneous resolution of their diverticula in association with VUR more frequently than boys. In his review of 304 patients with VUR, Amar (1972) confirmed the lesser resolution rate in boys. He attributed it to higher voiding pressures even without the presence of infravesical obstruction. A primary paraureteral diverticulum does not preclude

endoscopic subureteral injection of dextranomer/hyaluronic acid (Deflux) for correction of VUR (Perez-Brayfield et al., 2003).

Posterolateral and Multiple Congenital Diverticula.

These diverticula are often found in children with generalized connective tissue diseases, such as Ehlers-Danlos, Williams, or Menkes syndrome, but are occasionally seen in the absence of a known genetic syndrome (Babbitt et al., 1979; Garat et al., 2007; Hebert and Martin, 2015; Levard et al., 1989)**. These diverticula can become massive and many times fill larger than the bladder itself** (Figs. 30.4 and 30.5)**. Interestingly, pathological analysis does not necessarily show the classic herniation of mucosa through a bladder muscle defect but instead an attenuated muscle wall, allowing laxity in the absence of obstruction** (Garat et al., 2007).

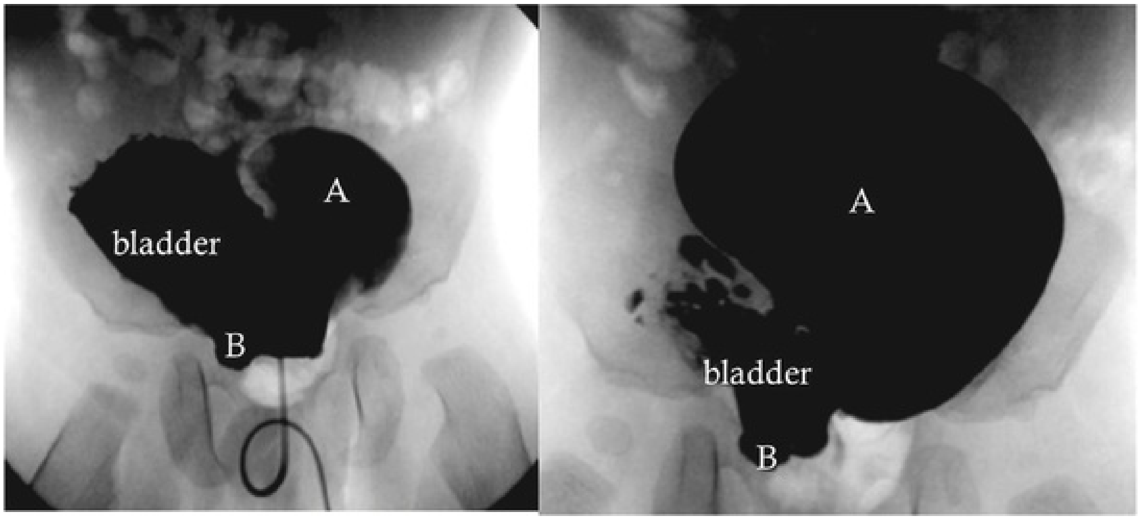

FIG. 30.4 In the left panel, the voiding cystourethrogram demonstrates the large superior diverticulum (A) and a smaller one posteriorly near the bladder neck (B). In right panel, postvoid film reveals the residual urine volume within the diverticulum.

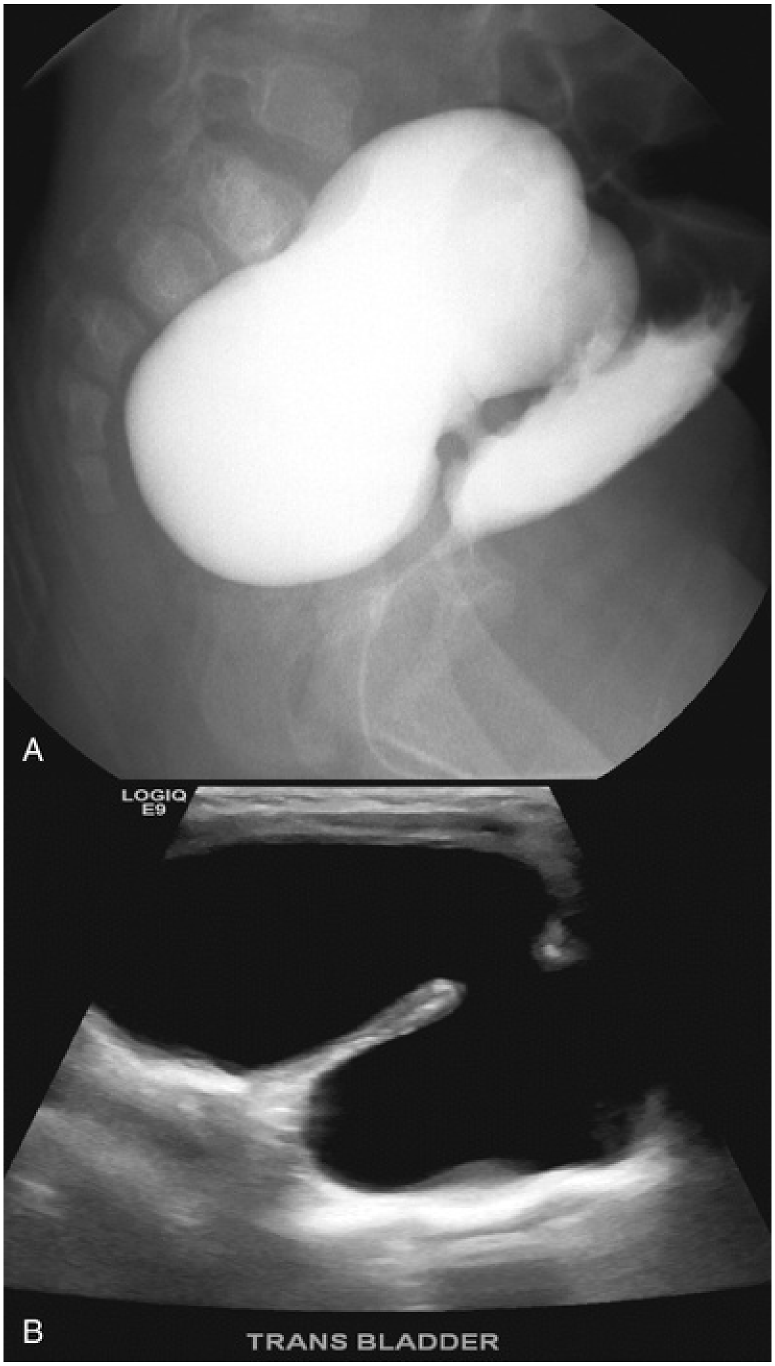

FIG. 30.5 Primary isolated posterolateral diverticulum in a newborn. (A) VCUG with diverticulum seen larger than the bladder. (B) Sonogram of the same diverticulum.

The most common presenting symptom is recurrent urinary tract infections (UTIs) resulting from poor emptying or urinary stasis in the diverticula. These can even lead to stone formation. If the child is asymptomatic, then close observation is recommended, especially in the setting of the earlier-mentioned connective tissue disorders. However, resection can be performed successfully using standard open or laparoscopic approaches in eliminating recurrent UTIs and many times improving spontaneous voiding. Unfortunately, recurrence or formation of new diverticula is common in syndromic patients, so surgical treatment must be carefully weighed with quality-of-life considerations. In some cases, urinary diversion with vesicotomy or suprapubic drainage may be preferred. Urodynamics should be pursued postoperatively to assess for any obstruction or high-pressure voiding that could expedite recurrence.

Key Points: Congenital Bladder Anomalies

- Persistent megacystis in the background of oligohydramnios is concerning for LUTO; megacystis that resolves before delivery may not have any postnatal sequela.
- Megacystis microcolon intestinal hypoperistalsis syndrome may have only megacystis noted prenatally.
- Nondilated anomalies are the most severe forms of congenital urologic malformations, such as bladder exstrophy. Usually normal amniotic fluid levels are found.
- Bladder agenesis is compatible with life only if the ureters drain ectopically.
- Children with connective tissue disorders can have multiple bladder diverticula that may require treatment because of stasis-related infections or stones.

Urachal Anomalies

The treatment of a symptomatic urachal remnant in a child typically requires complete surgical excision with a bladder cuff. This is a fairly simple operation performed either open or laparoscopically with low morbidity. It is the asymptomatic incidental urachal remnant that presents a clinical conundrum. Although urachal adenocarcinoma in a child is unreported, malignant transformation in an adult can be devastating with a high mortality and a much more complicated surgical excision. Ashley et al. (2007) have advocated for excision of all childhood urachal remnants when discovered regardless of symptoms to avoid potential adult progression; however, Gleason et al. (2015) were able to better quantify the risk of progression and recommend excision only in cases of symptomatic presentation (Fig. 30.6).

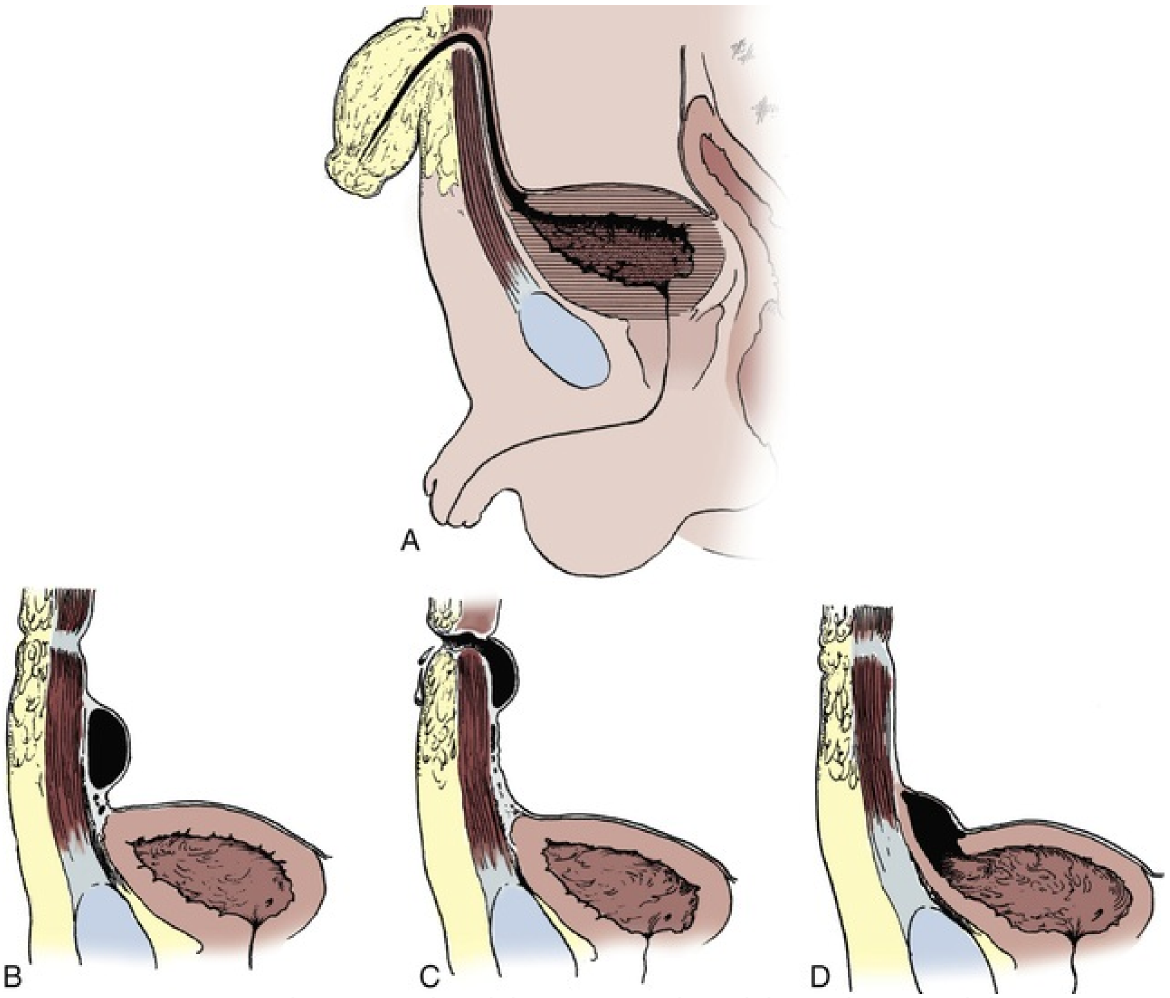

FIG. 30.6 Urachal anomalies. (A) Patent urachus. (B) Urachal cyst. (C) Umbilical-urachus sinus. (D) Vesicourachal diverticulum.

Patent Urachus.

Patent urachus is explained by nondescent of the bladder or, more commonly, failure of the epithelial-lined urachal canal to obliterate. Bladder obstruction during fetal development has been blamed for the urachus remaining tubular. The fact that urachal patency is often absent with severely obstructed bladders in utero, however, casts doubt on this theory. In addition, only up to 14% of patients with a patent urachus have postnatal confirmation of in utero bladder obstruction (Mesrobian et al., 1997; Schreck and Campbell, 1972). Obliteration of the urachus may be independent from the level of bladder distention. Therefore retubularization, rather than primary patency, may be the cause for urinary drainage from the umbilicus. This theory is supported by reports of umbilical urinary fistulas in acquired bladder obstructions later in life (Berman et al., 1988; Schubert et al., 1982).

A patent urachus is suspected in the neonatal period by continuous or intermittent drainage of fluid from the umbilicus. The most common organisms cultured from the umbilical drainage include *Staphylococcus aureus, Escherichia coli, Enterococcus, Citrobacter,* and, rarely, *Proteus* species (Mesrobian et al., 1997). Additional manifestations include an enlarged or edematous umbilicus and delayed healing of the cord stump (Razvi et al., 2001; Schiesser et al., 2003). The diagnosis is confirmed by demonstration of the fluid-filled canal on longitudinal ultrasound or contrast filling on retrograde fistulogram or VCUG (Fig. 30.7; Mesrobian et al., 1997). MRI can aid in the diagnosis but usually depends on the bladder's filling status. It is important to differentiate the condition from a patent omphalomesenteric duct. The presence of both anomalies in the same patient is rare (Mendoza et al., 1968).

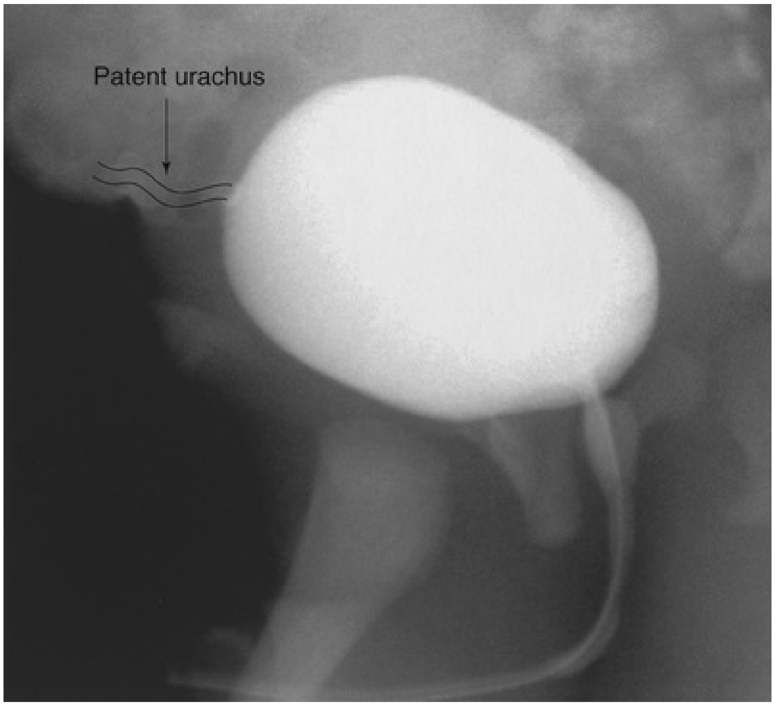

FIG. 30.7 Patent urachus. Vesicoureterogram image of patent urachus in a newborn. Retrograde contrast filling of patent canal with contrast pooling in umbilicus.

Management of an infected urachus with abscess formation includes

initial drainage under antibiotic coverage. Once the infection has subsided, complete excision of the patent urachus, including a bladder cuff, is required (Nix et al., 1958). It is important to remove all anomalous tissue. This avoids recurrences or stone formation and prevents the rare event of later transformation into a malignant adenocarcinoma (Ashley et al., 2007; Blichert-Toft and Nielsen, 1971; Goldman et al., 1988; Sheldon and Essig, 1994; Upadhyay and Kukkady, 2003).

Traditionally, the patent urachus is surgically excised using a transverse or midline infraumbilical incision. Before surgery, a balloon catheter is used to distend the bladder. In infants, a small transverse subumbilical incision is often possible because the bladder dome is still high. A feeding tube or small catheter is placed into the patent urachus for better intraoperative identification. The urachus can be incised circumscriptly, without removing the umbilicus for cosmetic reasons. The rectus fascia is incised in a longitudinal fashion, muscles spread apart, and the dome of the distended bladder identified. The urachus is identified and isolated, and a vessel loop is placed. The dissection continues extraperitoneally toward the umbilicus until the previously incised umbilical portion is free and can be pulled into the surgical field. It is then removed. A bladder cuff including the urachal insertion is marked and excised using electrocautery. The bladder is closed watertight in two layers. The catheter can be left in place overnight and removed the following morning.

Alternatively, urachal remnants can be removed laparoscopically. This can be done even in children younger than 6 months of age (Cadeddu et al., 2000; Fahlenkamp et al., 1995; Khurana and Borzi, 2002; Turial et al., 2007). Khurana and Borzi (2002) described their laparoscopic experience with 4 children between 5 months and 10 years and found the procedure to be safe in children of all ages. Technically, they suggested a three-port approach, with the camera port in the midline between the umbilicus and the xiphoid and two working ports on either side in the upper quadrant. Turial et al. (2007) reported on 27 children with a median age of 4.7 years. Early in their series they inserted the camera port at the umbilicus with working ports into the right and left upper abdomen. Later they preferred to place the camera into the left lower abdominal wall, with 2-mm working ports at the left lower and upper abdomen for better visualization of the urachus at the umbilicus. They reported no intraoperative or postoperative complications, no recurrences, and a median operating time of 35 minutes.

The advantage of the laparoscopic technique is the good visualization of the course of the urachus and the bladder dome. However, laparoscopic techniques require an intra-abdominal approach and pose the potential risk for spilling infected or malignant material into the abdominal cavity as well as intraperitoneal urinary extravasation. Robotic-assisted removal and single-port laparoscopy also have been suggested (Ahmed et al., 2017).

Urachal Sinus.

In the umbilical-urachus sinus, the urachus obliterates at the bladder level but remains open at the umbilical site, causing a continuously draining sinus. The manifestation is similar to that of the patent urachus. The diagnosis is made by sinugram. The caudal part of the urachus is filled with desquamated epithelial cells, and no connection to the bladder can be identified. **The presence of a persistent omphalomesenteric duct has to be considered. This would manifest as a Meckel diverticulum connected to the umbilicus. These structures can be very difficult to differentiate from an umbilical-urachus sinus because no connection to the bladder or bowel can be seen on sinugram. However, the surgical approach to both anomalies requires the complete excision of all tissue.** Unlike urachal structures, omphalomesenteric remnants can show gastric or small bowel mucosa on histologic examination.

Urachal Cyst.

There is no communication of the cyst with the bladder or umbilicus. However, the fluid-filled cyst can drain through the umbilicus or into the bladder intermittently. Urachal cysts are found more commonly in the distal part of the urachus and manifest more commonly in adults than in infants or children (Cilento et al., 1998). The cyst material consists of desquamated epithelial cells. These cells can become infected; *Staphylococcus aureus* has been identified as the most common organism (Mesrobian et al., 1997).

Once infected, urachal cysts can manifest as umbilical abscess formation or bladder infections. Additional symptoms include localized lower abdominal pain, voiding symptoms, or even a painful palpable mass. The diagnosis is confirmed by ultrasound, demonstrating the localized cyst between the anterior abdominal wall and the peritoneum. In a case of massive infection or difficult manifestation, a CT or MRI can clarify the anatomy and extent of disease (Berrocal et al., 2002). If unrecognized, the infected cyst can perforate into the bladder (Maruschke et al., 2003) or peritoneal cavity. This can cause peritonitis and formation of an enteric fistula (Ohgaki et al., 2003; Quek et al., 2003) Treatment consists of draining the infected cyst, followed by complete excision of the urachal remnant structures.

Urachal Diverticulum.

The urachus obliterates almost completely, except at the level of the bladder apex. Here it forms a diverticulum of varying size. These lesions are usually asymptomatic and found incidentally on nonrelated radiographic workups. Although the diverticula can enlarge in the case of urinary obstruction, this rarely causes problems because they tend to have a large opening and drain into the bladder well. Stone formation and urinary tract infections have been reported, especially in the case of a narrowed neck causing the need for intervention.

Key Points: Urachal Anomalies

- Urachal anomalies are usually detected postnatally because of umbilical drainage.
- Infected urachal remnants are treated with antibiotics followed by surgical excision.
- Urachal remnant can be confused for a persistent omphalomesenteric duct on preoperative workup.
- Asymptomatic, incidentally found urachal remnant excision should be discussed with the family because of the potential for malignant transformation as an adult.

Acquired Bladder Anomalies in Children

Noninflammatory Acquired Conditions

Acquired Diverticula

Acquired diverticula are the result of infravesical obstruction, which has to be addressed first. After bladder outlet resistance is normalized, diverticulectomy may become unnecessary because of natural remodeling of the bladder. If symptomatic, the diverticulum should be excised with ipsilateral ureteral reimplantation if it is near or included in the diverticulum. This can be successfully performed intravesically or extravesically and open or laparoscopically/robotically (Christman and Casale, 2012; Jayanthi et al., 1995; Yu, 2002).

Secondary paraureteral diverticula are acquired and develop as a result of existing infravesical obstruction or a neurogenic bladder as originally described by Hutch (1961)**. The resulting increased infravesical pressure forces the bladder mucosa to bulge between the muscle fibers. These diverticula are usually just one of many pop-off mechanisms that can occur throughout the bladder.** These diverticula also can be caused by weakening in the bladder muscle by infection (Barrett et al., 1976) or development of a muscular defect after bladder surgery (Sheu et al., 1998).

In both types of paraureteral diverticula, the Waldeyer's sheath eventually becomes damaged as the diverticulum expands in size. The increasing diverticulum pulls the intravesical ureter out of its anchored position, causing dysfunction of the ureterovesical junction. Eventually, the enlarged diverticulum can become responsible for ureteral obstruction. This even has been associated with renal dysplasia (Amar, 1972; Livne and Gonzales, 1985).

Paraureteral diverticula or posterolateral diverticula can become so large that they compress the bladder neck or posterior urethra. The resulting bladder outlet obstruction starts a vicious circle by continuously filling and expanding the diverticulum. This increases the obstruction and subsequently causes complete urinary retention (Sheldon and Essig, 1994; Zia-Ul-Miraj, 1999). This can be seen with the congenital diverticular syndromes discussed previously, leading to surgical intervention.

Bladder Hemangiomas

These benign vascular tumors are mostly seen in association with Klippel-Trenaunay or Sturge-Weber syndromes. They are typically solitary and less than 3 cm in diameter but can be multifocal. They are typically discovered because of gross hematuria with or without irritative voiding symptoms. Treatment can safely be performed with bladder biopsy with fulguration or neodymium:yttrium-aluminum-garnet (Nd:YAG) laser irradiation for small tumors, or partial cystectomy if large or concern for rapid blood loss (Cheng et al., 1999; Numanoğlu and Tatli, 2008).

Fibroepithelial Polyps

Although rare in the bladder, fibroepithelial polyps can be a cause of hematuria and irritative voiding symptoms. There have been case reports citing bladder outlet obstruction, ureteral obstruction, and bladder irritation. **A review of 21 years of bladder tumor specimens at Children's Hospital of Philadelphia revealed fibroepithelial polyps to be the second most frequent bladder tumor after rhabdomyosarcoma** (Huppmann and Pawel, 2011)**. Simple endoscopic resection is typically curative.**

Inflammatory Acquired Conditions

Nephrogenic Adenoma and Cystitis Cystica

Nephrogenic adenoma of the urinary bladder is a rare benign tumor mostly found in adults. Sporadic case reports in children describe the lesion as a reaction to infection, lithiasis, trauma, or surgery. Heidenreich et al. (1999) found a significant predominance of girls compared with boys (5 : 1), typically with hematuria or irritative bladder symptoms. The diagnosis is established after cystoscopy with biopsy. **Treatment consists of transurethral fulguration or resection of isolated nephrogenic adenomas. Although malignant transformation was not reported, tumor recurrence developed in 80% of the children, with a latency period of 4 years** (Heidenreich et al., 1999). Resection of nephrogenic adenoma followed by successful long-term resolution using ibuprofen and trimethoprim-sulfamethoxazole also has been described (Voss and Peppas, 2013).

Hungerhuber et al. (2008) reported a rare case of an adenocarcinoma in a 25-year-old patient who developed a neurogenic bladder after a car accident. He subsequently developed a nephrogenic adenoma, which was resected several times. Although the initial pathological finding was benign, a moderately differentiated adenocarcinoma was found after several resections. He underwent a radical cystectomy and remained tumor free (Hungerhuber et al., 2008).

Kao et al. (2013) reviewed 21 cases of nephrogenic adenomas from urinary bladder biopsies. Most patients had a history of bladder augmentation with recurrent stone formation and infections. The immunohistochemical profile suggested that nephrogenic adenomas are derived from distal tubular cells (Kao et al., 2013).

Cystitis cystica can present a similar picture of fluid-filled cystic masses in response to chronic inflammation. Cystitis cystica is best treated with long-term antibiotic prophylaxis. This disease process is almost exclusively in females. Cystitis glandularis is even rarer in children and occurs because of metaplasia of mucus-secreting epithelium. There has been concern of this being a premalignant lesion; however, few data are available to support this claim (Bastianpillai et al., 2018).

Eosinophilic Cystitis

Eosinophilic cystitis in children is sporadically described in case reports with a predominance in boys. **The cause remains unclear, and the histopathological examination includes inflammatory cells with numerous eosinophils throughout all layers of the bladder wall** (Tsakiri et al., 2004)**. Manifesting symptoms include dysuria, hematuria, suprapubic pain, and urinary retention. The diagnosis is made by cystoscopy with transurethral biopsy of the lesion, which has no “typical” appearance** (Fig. 30.8). Immunologic diseases and allergies have been suggested to be causative for the development of the lesions. In a large review of 135 cases, van den Ouden (2000) found transurethral resection combined with corticosteroids, antihistamines, or antibiotics to be most successful for all age groups. In neonates and young children, the disease can be self-limited and observation is justified (Al-Omar et al., 2005). In a case series of 4 patients between 5 days and 18 years, all were diagnosed by biopsy after clinical suspicion and were successfully treated with a combination of steroids, antihistamines, and antibiotics (Sparks et al., 2013).

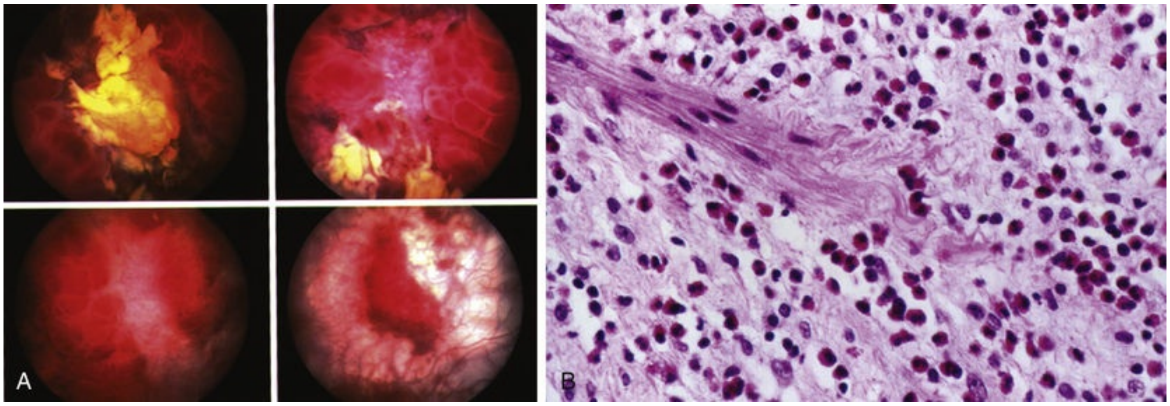

FIG. 30.8 Eosinophilic cystitis. (A) Cystoscopic views of lesion detected as mass on ultrasound in teenage male with severe dysuria and gross hematuria. (B) Biopsy of mucosal lesion demonstrating eosinophilic infiltrate and no evidence of malignancy.

Hemorrhagic Cystitis

Hemorrhagic cystitis in children is almost always in relation to treatment for childhood malignancies especially hematologic. Cyclophosphamide or ifosfamide treatment is the most common risk factor, but this is thought to be exacerbated by viral infections such as BK virus, cytomegalovirus, and adenovirus in the immunocompromised child. Pelvic radiation can also lead to significant hemorrhagic cystitis. Urothelial toxic agents such as cyclophosphamide are now given with mercaptoethane sulfonate sodium (mesna) to prevent significant bleeding. **Bladder irrigation can be difficult and traumatic in these children because of the limited catheter sizes that can be used. Duthie et al. (2012) have shown improved success with an early detection protocol, catheter avoidance, and addition of oral sodium pentosan polysulfate.** This shows great promise and a way to avoid further trauma in these children (Duthie et al., 2012).

Key Points: Acquired Bladder Anomalies in Children

- Acquired bladder diverticula can become large enough to cause urinary obstruction or create stasis leading to recurrent UTIs.
- After resection of nephrogenic adenomas, routine cystoscopy is necessary because of an 80% recurrence rate in children.

- Cystitis cystica can mimic a bladder tumor and is best treated with long-term antibiotic prophylaxis.
- Eosinophilic cystitis has no “typical” appearance and requires biopsy for diagnosis.
- Cyclophosphamide therapy can lead to hemorrhagic cystitis. For prevention, mesna is given simultaneously, and oral sodium pentosan polysulfate shows promise.

Acknowledgments

We would like to recognize and thank Dr. Dominic Frimberger and Dr. Bradley Kropp for their exceptional and thorough work on the prior editions of this chapter. Much of their writing has been included in this edition and updated where applicable.

Exstrophy-Epispadias Complex

John P. Gearhart MD, Heather N. Di Carlo MD

The exstrophy-epispadias complex of genitourinary malformations can be as simple as a glanular epispadias or an overwhelming multisystem defect such as cloacal exstrophy (Fig. 31.1). This chapter provides a comprehensive overview of the entire bladder exstrophy–epispadias–cloacal exstrophy spectrum. In addition, all modern methods of exstrophy management and their complications and outcomes are discussed.

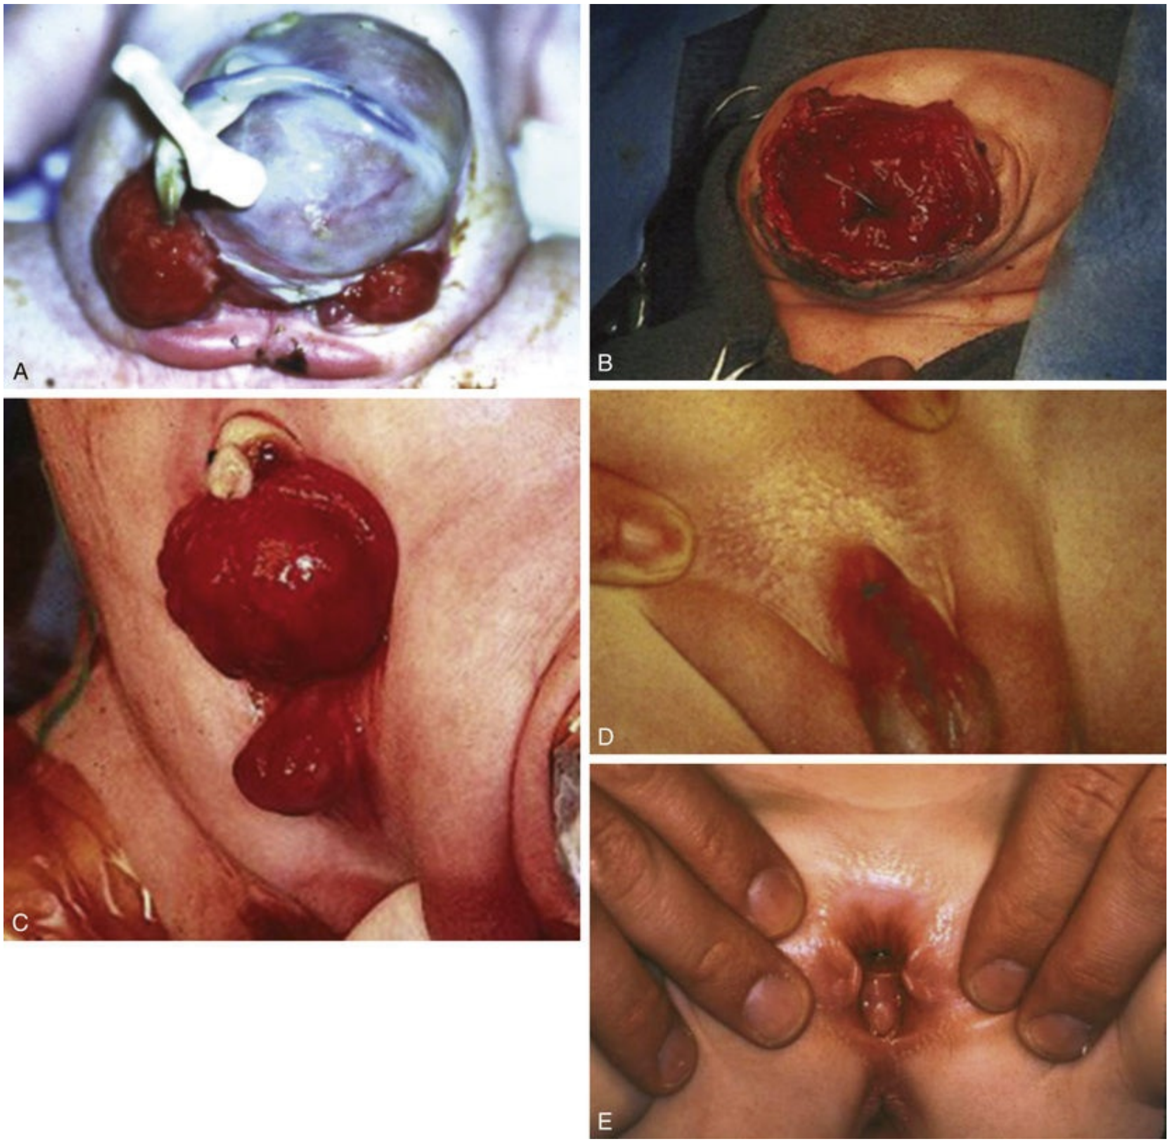

FIG. 31.1 Entities that constitute the exstrophy-epispadias complex. (A) Cloacal exstrophy. (B) Superior vesical fissure. (C) Classic bladder exstrophy. (D) Male epispadias. (E) Female epispadias.

Historical Aspects

In older texts, the first account of bladder exstrophy was ascribed to Assyrian-Babylonian sources dating from the first and second millennia BCE. At that time, birth anomalies in humans and animals were carefully recorded on tablets for their importance as omens, based on their interpretation by divination experts. Feneley and Gearhart (2000) examined Assyrian-Babylonian descriptions of congenital anomalies from cuneiform texts at the British Museum in London. Although references to anomalies involving the external genitalia were frequent (e.g., hermaphroditism, absence of external genitalia, unilateral and bilateral undescended testes), references to renal and bladder anomalies were few and difficult to interpret medically. Duplication and laterality of anomalies were described in detail because of their distinct significance, but malformations in combination were not recorded. On the basis of these studies performed with a prominent Assyriologist, a definitive description of bladder or cloacal exstrophy was not corroborated. **The first described case of epispadias is attributed to the Byzantine emperor Heraclius (CE 610–641), and the first description of cloacal exstrophy to Schenck in 1595** (Feneley and Gearhart, 2000).

Incidence and Inheritance

The incidence of bladder exstrophy is estimated to be 2.15 cases per 100,000 live births in the United States (Nelson et al., 2005a; Siffel et al., 2011). An internationally conducted prospective study places the incidence of bladder exstrophy at 1/46,000 live births (Cervellione et al., 2015). The male-to-female ratio of bladder exstrophy derived from multiple series is 2.3 : 1 (Shapiro et al., 1984). However, two series reported a 5 : 1 to 6 : 1 male-to-female ratio of exstrophy births (Ives et al., 1980; Lancaster, 1987).

The risk of recurrence of bladder exstrophy in a given family is approximately 1 in 100 (Ives et al., 1980). Shapiro et al. (1985) in a questionnaire identified the recurrence of exstrophy and epispadias in only 9 of approximately 2500 indexed cases. Lattimer and Smith (1966) cited a set of identical twins with bladder exstrophy and another set of twins in whom only one child had exstrophy. Shapiro's series identified five sets of male and female nonidentical twins in whom only one twin was affected with exstrophy; five sets of male identical twins in whom both twins were affected; one set of identical male twins in whom only one twin was affected; and three sets of female identical twins in whom only one twin had the exstrophy anomaly (Shapiro et al., 1984). Reutter et al. (2003) have demonstrated six families with two occurrences of the exstrophy-epispadias complex, one in which the proband was the product of a consanguineous union and four discordant twin pairs. Also, Boyadjiev et al. (2004a) found four multiplex families (2.7%) in a cohort of 151 families with the exstrophy-epispadias complex. There were three twin pairs, two of which were monozygotic, and concordance was present in only one of the twin pairs. Consanguinity was present in one family. Bladder exstrophy or epispadias was not reported until the 1980s in the offspring of parents with the exstrophy-epispadias complex. **Shapiro et al.** (1984) **determined that the risk of bladder exstrophy in the offspring of individuals with bladder exstrophy and epispadias is 1 in 70 live births, a 500-fold greater incidence than in the general population.** Boyadjiev et al. (2004a) studied sibling data from 200 families and found 259 unaffected children in addition to the probands with exstrophy. Twenty-six probands had first-, second-, or third-degree relatives with congenital anomalies unrelated to the exstrophy-epispadias complex, most of which were midline defects and oral clefts. Four probands had a total of seven biologic children who were unaffected. Data from Boyadjiev et al. (2004a) indicate that the average maternal age for exstrophy mothers was 34 years and the average paternal age was 32 years. In addition, 49% of probands were born from first pregnancies. This may represent societal changes indicating advancing maternal age for first pregnancies and increased risk of exstrophy when assisted reproductive techniques are used (Wood et al., 2003).

A (2011) multi-institutional study from North America and Europe involving an analysis of 441 families divided the study into mild epispadias (n = 43), intermediate-classic exstrophy (n = 366), and severe (cloacal) exstrophy (n = 31). Males were over-represented in all groups. Cleft lip and cleft palate were seen in a high prevalence. Maternal smoking during the first trimester was associated closely with cloacal exstrophy, and maternal preconception folic acid supplementation was associated with the mildest phenotype (epispadias) (Reutter et al., 2011).

Exploration of possible causes for the exstrophy-epispadias complex continues. A report from Israel indicated a 10-fold increase in exstrophy births to mothers who had received large doses of progesterone in the early part of the first trimester. Wood et al. (2003) reported on a sizable series of children with exstrophy conceived using assisted reproductive techniques. A 7.5-fold increase in incidence was noted when in vitro fertilization (IVF) was used. These two reports indicate a role for hormonal changes in the cause of the exstrophy-epispadias complex. In a large series of 214 females, no association with parental age, maternal reproductive history, or periconception maternal exposure to alcohol, drugs, radiation, or infections was found (Gambhir et al., 2008). However, periconception maternal exposure to smoking was significantly more common in patients with cloacal exstrophy than in the combined group of patients with classic exstrophy-epispadias.

Genetic studies to identify a genetic locus for the exstrophy-epispadias complex are underway. **Boyadjiev et al.** (2004b) **have reported finding a breakpoint disruption in the 5′ region of the *CASPR3* gene on chromosome 9. This observation is the first to suggest a possible genetic basis for development of the exstrophy-epispadias complex.** In another recent study by Ludwig et al. (2009), risk loci for the exstrophy spectrum were found in seven separate chromosomes, with susceptibility genes in several regions. *P63*, a member of the *p53* tumor suppressor gene, has been implicated in the potential association with bladder exstrophy. The N-terminal truncated isoform of p63, ΔNp63, promotes stem-cell proliferation while inhibiting apoptosis and may play a role in the development of abdominal and ventral bladder wall (Cheng et al., 2006). Compared with patients with normal control, bladder exstrophy patients have been shown to have decreased ΔNp63 expression in the bladder epithelium (Wilkins et al., 2012). Still, no genomic mutations of *p63* have yet been identified in bladder exstrophy patients (Ching et al., 2010).

Qi et al. (2011) used genome-wide expression profiling to identify 162 bladder exstrophy-epispadias complex candidate genes that had twofold or higher expression differences between exstrophic and normal bladder smooth muscles in mouse and human embryologic bladder tissues. They also found 16 candidate genes that are expressed in the infraumbilical endoderm and mesoderm. Most of these genes have functions related to cellular assembly, musculoskeletal system development, and connective tissue morphology. Specifically, 30% of these genes were related to the desmosomal structure and cytoskeleton assembly, of which 69% were underexpressed in exstrophic bladders. In this study, the two most downregulated genes in exstrophic bladders, desmin and desmuslin, encode muscle-specific proteins that interact with desmoplakin, the sixth most overexpressed gene in exstrophic bladders. New data from Ching et al. (2010) and Qi et al. (2013) have shown significant dysregulation of *p63* in tissue from newborns with bladder exstrophy. More recent developments in genome-wide association studies implicate other potential gene loci responsible for bladder exstrophy. For example, the *ISL 1* gene located on chromosome 5q11.1, which encodes a LIM zinc-binding/homeobox-domain transcription factor, has been shown to have association with bladder exstrophy. In murine models, this gene has shown a developmental role in the genital area, thus providing additional evidence for a susceptibility gene (Draaken et al., 2015). *ISL 1* was further implicated in association with classic bladder exstrophy (CBE) in a large genome-wide association case-control study of 268 CBE patients and 1354 matched controls. A meta-analysis of a small nucleotide polymorphism marker located at the *ISL 1* locus of chromosome 5q11.2 was significantly associated with CBE ($P < 0.001$) (Zhang et al., 2017). *ISL 1* has been shown to regulate factors associated with development of the genital tubercle, such as Bmp4, Fgf10, and Wnt5a (Ching et al., 2018). Continuing research in this cutting edge field will provide more clarity into the role of genetics in exstrophy.

Embryology

Bladder exstrophy, cloacal exstrophy, and epispadias are variants of the exstrophy-epispadias complex (see Fig. 31.1). The cause of this complex is thought to be the failure of the cloacal membrane to be reinforced by ingrowth of mesoderm (Muecke, 1964). The cloacal membrane is a bilaminar layer situated at the caudal end of the germinal disk that occupies the infraumbilical abdominal wall. Mesenchymal ingrowth between the ectodermal and endodermal layers of the cloacal membrane results in formation of the lower abdominal muscles and the pelvic bones. The cloacal membrane is subject to premature rupture, and, depending on the extent of the infraumbilical defect and the stage of development during which the rupture occurs, bladder exstrophy, cloacal exstrophy, or epispadias results (Ambrose and O'Brien, 1974).

After mesenchymal ingrowth occurs, the urorectal septum grows in a caudal direction and divides the cloaca into a bladder anteriorly and a rectum posteriorly (Fig. 31.2). Distally, the septum meets the posterior remnant of the bilaminar membrane, which eventually perforates and forms the urogenital and anal openings. The paired genital tubercles migrate medially and fuse in the midline, cephalad to the dorsal membrane before perforation.

The theory of embryonic maldevelopment in exstrophy held by Marshall and Muecke (1968) **is that the basic defect is an abnormal overdevelopment of the cloacal membrane during the fourth week of gestation, which prevents medial migration of the mesenchymal tissue and proper lower abdominal wall development.** The timing of the rupture of this defective cloacal membrane determines the variant of the exstrophy-epispadias complex that results. Classic exstrophy accounts for more than 50% of the patients born with this complex (Marshall and Muecke, 1968; Muecke, 1964). Martinez-Frias et al. (2001), using epidemiologic factors of low birth weight, twinning, single umbilical artery, and associated defects, postulated that cloacal exstrophy and exstrophy of the bladder are two different expressions of a primary developmental field defect; cloacal exstrophy is an early defect. It has been postulated that one or both of the lateral body wall folds fail to move far enough ventrally to meet its counterpart in the midline (Sadler and Feldkamp, 2008).

Thus, if closure fails in the abdominal and pelvic region, cloacal exstrophy results, and if failure occurs in the pelvis alone, classic exstrophy occurs.

Other plausible theories concerning the cause of the exstrophy-epispadias complex exist. Abnormal development of the genital hillocks caudal to the normal position, with fusion in the midline below rather than above the cloacal membrane, has been embraced by other investigators (Ambrose and O'Brien, 1974; Patton and Barry, 1952). Another interesting hypothesis that remains controversial describes an abnormal caudal insertion of the body stalk, which results in a failure of interposition of the mesenchymal tissue in the midline (Mildenberger et al., 1988). As a consequence of this failure, translocation of the cloaca into the depths of the abdominal cavity does not occur. A cloacal membrane that remains in a superficial infraumbilical position represents an unstable embryonic state with a strong tendency to disintegrate (Johnston and Kogan, 1974), which has been supported by the laboratory work of Thomalla et al. (1985).

Another interesting theory is that maldevelopment of the bony pelvis rather is the inciting issue for the development of exstrophy. Beaudoin et al. (1997) have suggested that lack of “rotation” of the pelvic ring primordium prevents structures attached to the pelvic ring from joining in the midline, allowing herniation of the bladder to occur. The cause of this inadequate rotation remains elusive.

Key Points: The Exstrophy-Epispadias Complex

- The incidence of bladder exstrophy in the United States is estimated to be 2.15 cases per 100,000 live births.
- Bladder exstrophy, cloacal exstrophy, and epispadias are variants of the exstrophy-epispadias complex.
- In classic bladder exstrophy, most anomalies are related to defects of the abdominal wall, bladder, genitalia, pelvic bones, rectum, and anus.
- The male genital defect is severe and remains the most troublesome aspect of the surgical reconstruction.
- In females, the vagina is shorter than normal, hardly greater than 6 cm in depth, but of normal caliber. The vaginal orifice is frequently stenotic and displaced anteriorly, the clitoris is bifid, and the labia, mons pubis, and

clitoris are divergent.

Classic Bladder Exstrophy

Anatomic Considerations

Exstrophy of the bladder is part of a spectrum of anomalies involving the urinary tract, the genital tract, the musculoskeletal system, and sometimes the intestinal tract. In CBE, most anomalies are related to defects of the abdominal wall, bladder, genitalia, pelvic bones, rectum, and anus. Because of the involved nature of this defect, the deficits are described here as they affect each system.

Bony Pelvis and Spinal Defects

Formerly, CBE was thought to show only the characteristic widening of the pubic symphysis caused by malrotation of the innominate bones with an outward rotation or eversion of the pubic rami at their junction with the iliac bones. **However, modern imaging using three-dimensional (3D) computed tomography (CT) has demonstrated previously unknown rotational and dimensional abnormalities** (Sponseller et al., 1995). **Rotational anomalies include (1) external rotation of the posterior pelvis/iliac wings; (2) external rotation of the anterior pelvic segment; (3) coronal rotation of the sacroiliac joint; (4) acetabular retroversion; (5) convergence of iliac wings; and (6) femoral retroversion. Dimensional anomalies include (1) increased pubic diastasis; (2) shortened anterior pubic segment (30%); and (3) increased intertriradiate cartilage distance.**

Sponseller et al. (1995), using CT of the pelvis with 3D reconstruction, were the first to accurately characterize the exact bony defect associated with CBE and cloacal exstrophy. In reviewing a large group of patients with exstrophy of the bladder, using pelvic CT scans and age-matched controls, Sponseller et al. (1995) found that patients with CBE have a mean external rotation of the posterior pelvis of 12 degrees on each side, along with retroversion of the acetabulum, and a mean 18 degrees of external rotation of the anterior pelvis, along with 30% shortening of the pubic rami, in addition to the previously described diastasis of the symphysis pubis (Fig. 31.3). In long-term follow-up there was a foot progression angle of 20 to 30 degrees of external rotation beyond the normal limits seen in early childhood, which improves with age. Likewise, patients with cloacal exstrophy not only had pelvic deformities to a greater degree but also had asymmetry of the preceding parameters between the right and left sides of the pelvis, malformation of the sacroiliac joints, and occasional dislocations of the hip (Sponseller et al., 1995).

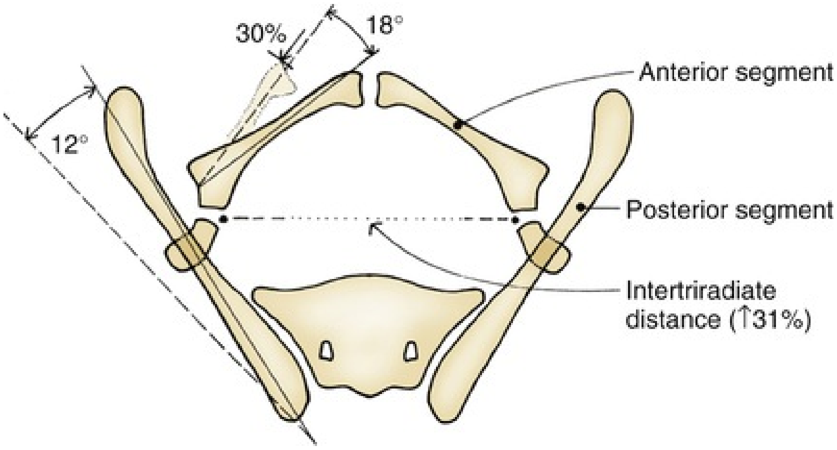

FIG. 31.3 Pelvic bone abnormalities noted in classic bladder exstrophy. The posterior bone segment is externally rotated (12 degrees mean on each side), but the length is unchanged. The anterior segment is externally rotated (18 degrees mean on each side) and shortened by 30%. The distance between the triradiate cartilage is increased by 31%.

Data from Stec et al. (2001a), who used 3D models from CT scans, found the sacroiliac joint angle (before closure) was 10 degrees larger than controls in the exstrophy pelvis, being 10 degrees more toward the coronal plane than sagittal (Fig. 31.4); the exstrophy pelvis had 14.7 degrees more inferior rotation than controls. In addition, the sacrum in exstrophy patients has a 42.6% larger volume and 23.5% more surface area than in controls.

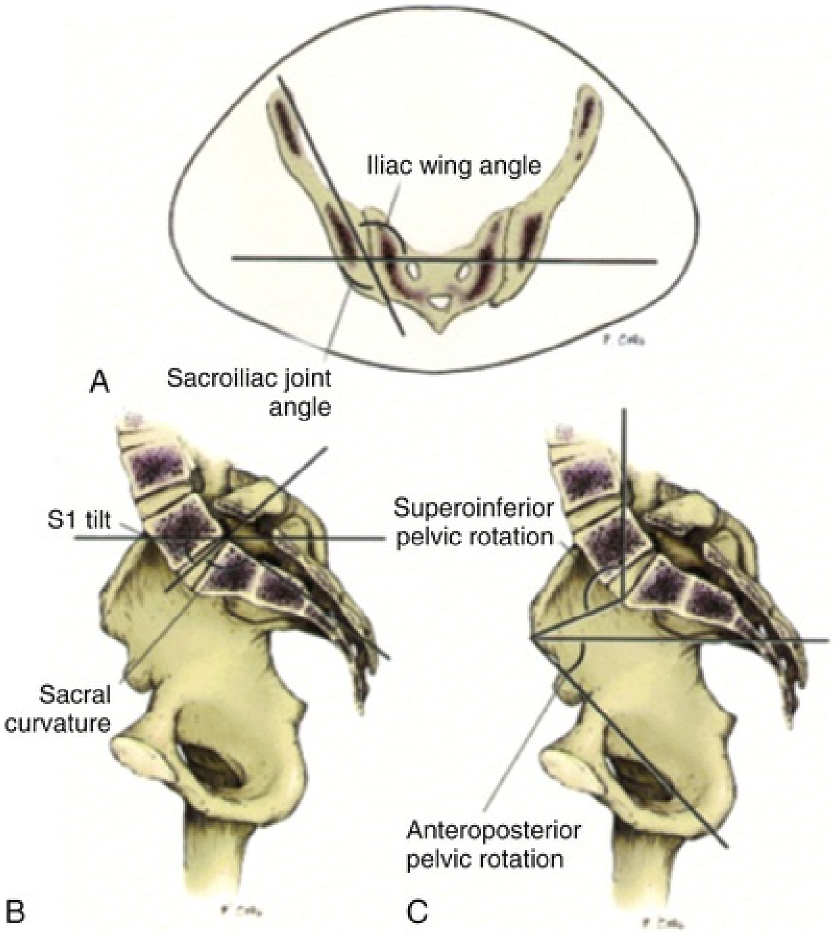

FIG. 31.4 Sacroiliac joint angles before closure in children with classic exstrophy 10 degrees larger than normal controls. The bony pelvis has 14.7 degrees inferior rotation compared with normal controls. (From Stec AA, Pannu HK, Tadros YE, et al: Evaluation of the bony pelvis in classic bladder exstrophy using 3D CT—further insights. *Urology.* 58:1030, 2001.)

These rotational deformities of the pelvic skeletal structures contribute to the short, pendular penis seen in bladder exstrophy. Outward rotation and lateral displacement of the innominate bones also accounts for the increased distance between the hips, waddling gait, and outward rotation of the lower limbs in these children, which causes little disability and usually corrects to some degree over time. The 30% shortage of bone in the exstrophy pelvis has largely gone unexplained. Studies by Stec and Gearhart (2003) about using sections from the entire bony pelvis in fetal exstrophy specimens and normal aborted fetuses reported that the ultrastructure, bone development, microscopic growth patterns, and endochondral ossification were absolutely the same. Thus restoration of the physiologic shape of the pelvis may lead to more normal bone growth, decreased shortage of bone, and a more appropriate distribution of the mechanical and developmental forces on a more closed, normally functioning pelvic ring.

The incidence of spinal anomalies in exstrophy had formerly not been well studied. A large study of 299 children with bladder exstrophy from a single center indicated spinal variations without clinical significance (spina bifida occulta, lumbarization or sacralization of vertebrae) in 11%, uncomplicated scoliosis in 2.7%, and spinal dysraphism in 4%, including myelomeningocele, lipomeningocele, scimitar sacrum, and hemivertebrae, but only 1 patient demonstrated any evidence of neurologic dysfunction (Cadeddu et al., 1997).

Pelvic Floor Defects

Stec et al. (2001b), using 3D models created from CT scans of children with CBE and normal age-matched controls, found that the puborectal slings were supporting two times more body cavity area than normal. The levator ani group is positioned more posteriorly in exstrophy patients, with 68% located posterior to the rectum and 32% anterior (vs. 52% posterior and 48% anterior in healthy controls) (Fig. 31.5). The levators are also rotated outward 15.5 degrees, and in the coronal aspect the levators are 31.7 degrees more flattened than normal. This deviation from normal makes the exstrophy puborectal sling more flattened than its normal conical shape. There was no significant difference in the length or thickness of these muscles between patients with exstrophy and controls.

A comparison of 3D magnetic resonance imaging (MRI) in children with exstrophy before closure and normal controls indicated that the levator ani group was less dome shaped and more irregular in those with exstrophy (Williams et al., 2004). Also, there was no relationship between the amount of pubic diastasis and the extent of disproportionate curvature of the levator ani group. In addition, Halachmi et al. (2003) reported on the postoperative appearance of the pelvic floor with 3D MRI. In 2 patients who had some degree of continence, the intrasymphyseal distance was shortest, the angle of the levator ani divergence more normal, and the bladder neck most deeply positioned in the pelvis. Gargollo et al. (2005), reporting on a mixed group of patients, noted that the puborectalis angle in those with dry intervals was decreased compared with that before closure. These 2 studies correlate well with earlier findings of Gearhart et al. (1993c) showing that in the adult patients who were dry, the puborectalis angle was less than 65 degrees. **Stec et al.** (2012c), **used 3D MRI to evaluate the pelvis before and after primary closure. Of the 19 patients, 12 had closure as newborns without osteotomy and 7 had closure outside of the newborn period with an osteotomy. The preoperative and postoperative MRIs revealed that closure (1) reshapes the pelvis from a boxlike configuration to a more inwardly rotated hammock; (2) redistributes a significant portion of the levator group into the anterior compartment; and (3) facilitates a smooth uniform contouring of the pelvic floor.** Quantitatively, this was demonstrated by 10- to 11-degree increase in the ischial angle and 6.0- to 6.2-degree decrease in the obturator internus angle. These data reinforce the necessity for aggressive dissection and posterior placement of the posterior vesicourethral unit into the pelvis and the role of pelvic osteotomy and pelvic fixation.

Abdominal Wall Anomalies

The triangular defect caused by the premature rupture of the abnormal cloacal membrane is occupied by the exstrophied bladder and posterior urethra. The fascial defect is limited inferiorly by the intrasymphyseal band, which represents the divergent urogenital diaphragm. This band connects the posterior vesicourethral unit to the pubic ramus on anatomic study. The anterior sheath of the rectus muscle has a fanlike extension behind the urethra and bladder neck that inserts into the intrasymphyseal band. Investigations into the relationship of the rectus muscle and fascia to the urogenital diaphragm (Wakim and Barbet, 2002) have found no gross or histologic evidence of the presence of any striated sphincter. However, clear evidence of bladder musculature extending laterally to the pubis was found where it interdigitates with fibers from the rectus fascia, forming the fibrous urogenital diaphragm (Wakim and Barbet, 2002). Gearhart et al. (1991) have shown the importance of radical incision of these fibers lateral to the urethral plate down to the level of the inferior pubic ramus and levator hiatus, and data from failed exstrophy closures show these fibers to be intact in many patients at the time of reclosure.

At the upper end of the triangular fascial defect is the umbilicus. In bladder exstrophy, the distance between the umbilicus and the anus is foreshortened. Because the umbilicus is situated well below the horizontal line of the iliac crest, there is an unusual expanse of uninterrupted abdominal skin. If an umbilical hernia is present, it is usually of insignificant size. The umbilical hernia is repaired at the time of the initial exstrophy closure. Omphaloceles frequently seen in cloacal exstrophy are rare in exstrophy and are usually small and closed at the time of bladder closure.

The frequent occurrence of indirect inguinal hernias is attributed to a persistent processus vaginalis, large internal and external inguinal rings, and lack of obliquity of the inguinal canal. Connolly et al. (1995), in a review of 181 children with bladder exstrophy, reported inguinal hernias in 81.8% of boys and 10.5% of girls. At the time of closure of the bladder exstrophy, these hernias should be repaired by excision of the hernial sac and repair of the transversalis fascia and muscle defect to prevent recurrence or a direct inguinal hernia. The contralateral side should also be explored because the incidence of synchronous or asynchronous bilaterality is 81.8% (Connolly et al., 1995). Recent data by Lavien et al. (2014) in a large group of 136 exstrophy closures clearly demonstrated that if pelvic osteotomy is used for the closure, the incidence of development of a hernia is lower and the risk of recurrence after repair is significantly lower.

Anorectal Defects

The perineum is short and broad and the anus is situated directly behind the urogenital diaphragm; it is displaced anteriorly and corresponds to the posterior limit of the triangular fascial defect. Data from Stec et al. (2011) found in a series of 678 patients with classic exstrophy an incidence of colorectal anomalies of 1.8%. The most common anomaly was imperforate anus, second was rectal stenosis, and third was congenital rectal prolapse. Although the incidence is low, it is a 72-fold increase compared with the general population.

Isolated colorectal abnormalities occur in roughly 2% of exstrophy patients, considerably more frequent than the general population. This most commonly manifests as imperforate anus, followed by rectal stenosis and rectal prolapse (Stec et al., 2011). The divergent levator ani and puborectalis muscles and the distorted anatomy of the external sphincter contribute to varying degrees of anal incontinence and rectal prolapse. Anal continence is usually imperfect at an early age. Rectal prolapse frequently occurs in untreated exstrophy patients and is usually transient and easily reduced. Prolapse disappears after bladder closure and pubic apposition. The appearance of prolapse in an infant is an indication to proceed with definitive management of the exstrophied bladder. **If rectal prolapse occurs at any time after exstrophy closure, posterior urethral or**

bladder outlet obstruction should be suspected, and immediate evaluation of the outlet tract by cystoscopy should be performed (Baker and Gearhart, 1998).

Male Genital Defect

The male genital defect is severe and remains the most troublesome aspect of the surgical reconstruction (Fig. 31.6). Formerly, it was thought that the individual corpora cavernosa were of normal caliber but appeared shorter because of the wide separation of the crural attachments, the prominent dorsal chordee, and the shortened urethral groove. **However, Silver et al.** (1997b) **described the genital defect for the first time in exacting detail. MRI was used in adult men with bladder exstrophy and compared with results for age- and race-matched controls.** It was found that the anterior corporeal length of male patients with bladder exstrophy was almost 50% shorter than that of normal controls (Fig. 31.7). However, although the posterior length of the corporeal body was the same as in age-matched controls, the diameter of the anterior corporeal segment was 30% greater than normal. Also, on MRI, although the diastasis of the symphysis pubis increased the intrasymphyseal and intercorporeal distances, the angle between the corpora cavernosa was unchanged because the corporeal bodies were separated in a parallel fashion. Therefore the penis appears short not only because of the diastasis of the pubic symphysis but also because of marked congenital deficiency of anterior corporeal tissue (Silver et al., 1997b). In a recent surgical anatomic study by Perovic and Djinovic (2008), precise description of the penile defect included (1) corporeal bodies separated and triangular in shape; (2) a long convex ventral surface and a short wedge-shaped dorsal surface; and (3) neurovascular bundle length determined by its lie on the individual corporeal bodies.

combined with the congenital deficiency of the anterior corporal tissue leads to the shorter appearance of the penis. *aCC,* Corpora cavernosa suspended angle; *ACL,* anterior corporal length; *Cdiam,* corpus cavernosum diameter; *ICD,* intercorporal distance; *ISD,* intersymphyseal distance; *PCL,* posterior corporal length; *TCL,* total corporal length.

In a study by Gearhart et al. (1993c), **13 adult men born with bladder exstrophy were evaluated with MRI of the pelvis to evaluate the size and configuration of the prostate and accessory sex organs. The volume, weight, and maximum cross-sectional area of the prostate appeared normal compared with published control values** (Fig. 31.8). In none did the prostate extend circumferentially around the urethra, and the urethra was anterior to the prostate in all patients. Silver et al. (1997a) reported free and total prostate-specific antigen (PSA) levels for a group of adult men with exstrophy. Although the levels were measurable, they were below the upper limits of established age-specific reference ranges for normal men. The vas deferens and ejaculatory ducts are normal in the exstrophy patient, and the mean seminal vesicle length in men is normal compared with published controls.

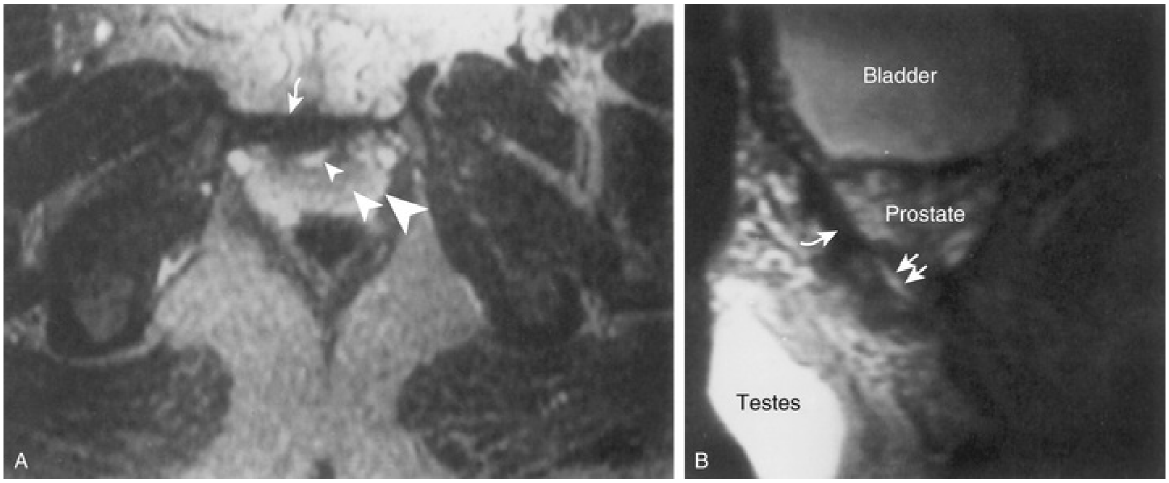

FIG. 31.8 (A) Axial T2-weighted image of the midprostate in a 20-year-old continent patient with bladder exstrophy. *Small arrowhead,* Lumen of the urethra; *medium arrowhead,* transitional zone; *large arrowhead,* peripheral zone. *Curved arrow,* Fibrous band of the intersymphyseal bar. (B) Sagittal T2-weighted image through the midprostate gland shows anterior urethra *(double arrows)* and posterior prostate gland. Intersymphyseal fibrous band *(curved arrow)* extends along the entire length of the prostate.

Autonomic innervation of the corpus cavernosum is provided by the cavernous nerves. These autonomic nerves are displaced laterally in

patients with exstrophy (Schlegel and Gearhart, 1989). These nerves are preserved in almost all exstrophy patients because potency is preserved after surgery. However, retrograde ejaculation may occur after bladder closure and/or bladder neck reconstruction.

Testis function has not been studied in a large group of postpubertal exstrophy patients, and it is generally believed that fertility is not impaired by testicular dysfunction. In 29 of the authors' adult exstrophy patients, all sperm harvested for in vitro fertilization had normal parameters. The testes frequently appear undescended in their course from the widened separated pubic tubercles to the flat, wide scrotum. Most testes are retractile and have an adequate length of spermatic cord to reach the scrotum without the need for orchiopexy.

Female Genital Defects

Reconstruction of the female genitalia presents a less complex problem than in the male (Fig. 31.9). **The vagina is shorter than normal, hardly greater than 6 cm in depth, but of normal caliber. The vaginal orifice is frequently stenotic and displaced anteriorly; the clitoris is bifid; and the labia, mons pubis, and clitoris are divergent. The cervix enters the vagina superiorly, so it lies in the anterior vaginal wall near the introitus. The fallopian tubes and ovaries are normal.** The clitoral halves should be joined and the two ends of the labia minora joined to make a fourchette at the time of primary closure. Vaginal dilation or episiotomy may be required to allow satisfactory intercourse in the mature female. Prior data by Stec et al. (2001b) and recent 3D ultrasound data by Ebert et al. (2009) show that although the levator hiatus has a normal anteroposterior length, it is almost two times wider than normal. This defective pelvic floor may predispose mature females to the development of uterine prolapse, making uterine suspension necessary. This usually occurs after childbirth but can occur even in the nulliparous patient. When studied in a large adult female population, 10 of 56 women developed uterine prolapse at a mean age of 16 years. Six patients had been managed with reconstruction that included a posterior iliac osteotomy (Mathews et al., 2003a). Mean age at the time of osteotomy was 2.1 years. Formerly, it was thought that osteotomy in the newborn or during early childhood would be protective against the development of uterine prolapse in adult life. However, new data from Anusionwu et al. (2013) in a large group of women with exstrophy showed that the width of the adult diastasis was the only factor on univariate analysis to predict adult prolapse.

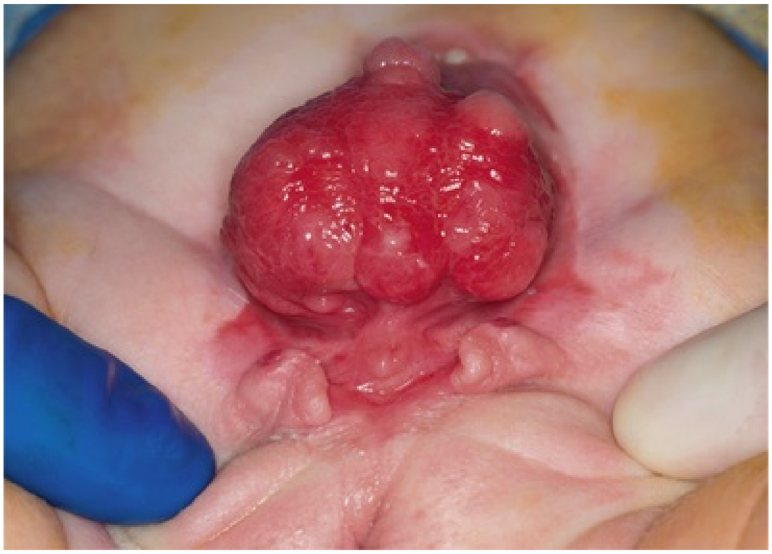

FIG. 31.9 Newborn girl with classic bladder exstrophy. Notice the open urethral plate, bifid clitoral halves, and anterior displacement of the vaginal orifice.

Benz et al. applied stereoscopic visualization techniques to 3D MRI reconstructions and made observations about genital and pelvic anatomy in females with CBE (Benz et al., 2018). By comparing the portion of the clitoral body attached to the pelvis to the portion in the anterior soft tissue, they found that the majority of the clitoral body is anterior to the pelvic attachment in female patients with CBE, contrary to the findings in normal patients and in males with CBE (Fig. 31.10).

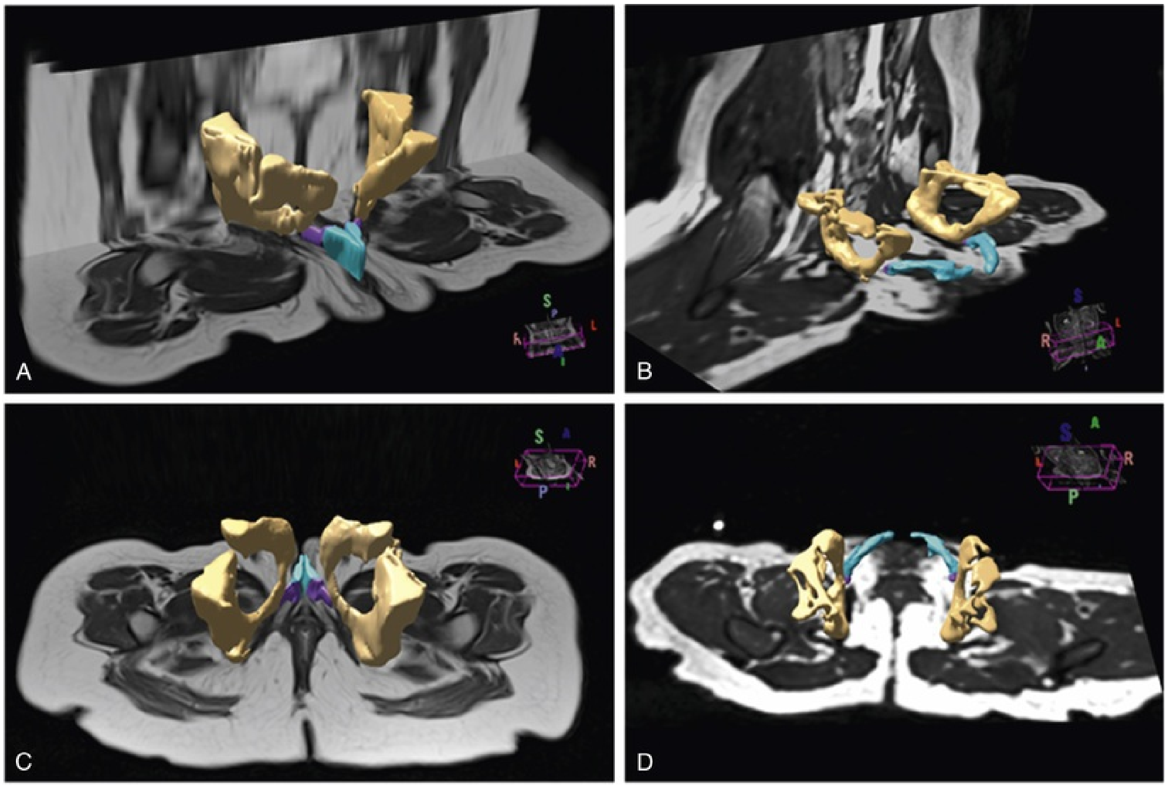

FIG. 31.10 Three-dimensional reconstruction of pelvic magnetic resonance imaging in normal female and bladder exstrophy patients. The coronal (A) and a superior-view axial (C) renderings show the pelvic and genital anatomy of 7-year-old female without exstrophy. The anterior and posterior (*blue* and *purple,* respectively) segments of the corpora cavernosa are shown. The coronal (B) and a superior-view axial (D) rendering of a female with bladder exstrophy patient before surgical repair is shown.

Urinary Defects

At birth, the bladder mucosa usually appears normal; but often hamartomatous polyps may be present on the bladder surface. The bladder mucosa should be frequently irrigated with saline and protected from trauma by some form of protective membrane before closure so that cystic or metaplastic changes in the mucosal surface do not occur.

The size, distensibility, and neuromuscular function of the exstrophied bladder, as well as the size of the triangular fascial defect to which the bladder muscles attach, affect the decision to attempt repair. In the past several years, multiple basic science studies have been published that further delineate the exact nature of the exstrophied bladder in the newborn. **One of the first papers to characterize the neuromuscular function of the bladder was published by**

Shapiro et al. (1985). **In their work, muscarinic cholinergic receptor density and binding affinity were measured in control subjects and in patients with CBE. The density of the muscarinic cholinergic receptors in the control and exstrophy groups were similar, as was the binding affinity of the muscarinic receptor.** Therefore the neurophysiologic composition of the exstrophied bladder is not grossly altered during its anomalous development. Studies have investigated the neural innervation of the newborn exstrophy bladder and its muscle and collagen content. Lee et al. (1996) looked at bladder biopsy specimens obtained from 12 newborns with bladder exstrophy, compared them with age-matched controls, and found an increase in the ratio of collagen to smooth muscle. Using anticollagen antibodies, they evaluated various types of collagen in these bladders and found there was no statistical difference in the amount of type I collagen in the bladders of newborns with exstrophy at initial closure, but there was a threefold increase in type III collagen. Peppas et al. (1999) found, in patients who gained adequate bladder capacities and were awaiting bladder neck reconstruction, that the ratio of collagen to smooth muscle decreased markedly after a successful closure and infection-free follow-up. Lais et al. (1996) reported similar findings and found that the ratio of smooth muscle to collagen increased after a successful closure.

In an extension of the studies just cited, Mathews et al. (1999b) **looked at the number of myelinated nerves per field in the bladders of normal newborn subjects and those with exstrophy. The average number of myelinated nerves per field was significantly reduced in the exstrophy bladders compared with controls. This reduction in nerve fibers appears to be the result of a lack of small fibers with preservation of larger nerve fibers. In light of the findings, it is believed that bladder exstrophy in a newborn represents an earlier stage of bladder development and differentiation.**

In a large study by Rosch et al. (1997), **multiple immunocytochemical and histochemical markers were examined in patients with epispadias or CBE. These studies involved indirect immunocytochemistry for vasoactive intestinal polypeptide (VIP), neuropeptide Y (NPY), substance P (SP), calcitonin gene–related peptide (CGRP), protein gene product (PGP) 9.5, and nicotinamide adenine dinucleotide phosphate diaphorase (NADPHd). No evidence of bladder muscle dysinnervation was found morphologically in any cases of CBE. Therefore, although a newborn with bladder exstrophy may have a maturational delay in bladder development, these bladders have**

the potential for normal development after a successful primary closure.

When the bladder is small, fibrosed, inelastic, and covered with polyps, functional repair may be impossible (Fig. 31.11). Novak et al. (2005) investigated the pathology and malignant potential of the polyps found in these small bladders. Two types of polyps were observed, with some overlap in findings: fibrotic and edematous. Both were associated with overlying squamous metaplasia in approximately 50% of cases. Varying degrees of von Brunn nests, cystitis cystica, and cystitis glandularis were noted. Cystitis glandularis was noted in a higher percentage of secondary closures. Because of the potential risk of adenocarcinoma associated with cystitis glandularis, future surveillance of these patients with urine cytology and cystoscopy as they enter adulthood is recommended. The more normal bladder may be invaginated or it may bulge through a small fascial defect, indicating the potential for satisfactory capacity after successful initial closure. Further investigation revealed that bladder polyps, particularly those that appear after a failure closure tend to impede bladder growth (Jayman et al., 2017). **Not until examination under anesthesia can the true defect be adequately evaluated because the depth of this bladder extension into the pelvis cannot be appreciated unless the patient is under anesthesia.**

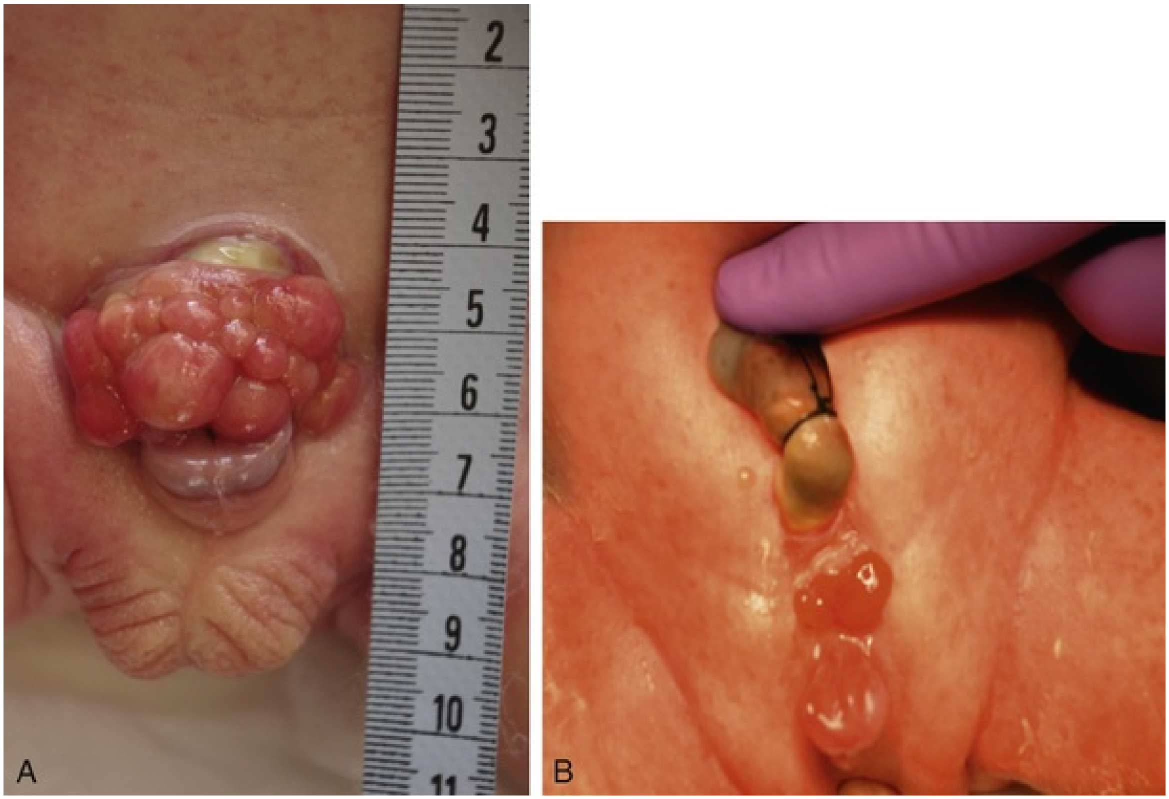

FIG. 31.11 (A) Small bladder template covered with polyps, unsuitable for closure. (B) Extremely small bladder template in newborn unsuitable for closure.

Bladder function was assessed in a group of continent exstrophy patients with normal reflexive bladders. Normal cystometrograms were obtained in 70% to 90% of patients (Toguri et al., 1987). Diamond et al. (1999), looking at 30 patients with bladder exstrophy at various stages of reconstruction, found that 80% of patients had compliant and stable bladders before bladder neck reconstruction. After bladder neck reconstruction, approximately half of the patients maintained normal bladder compliance and a lesser number maintained normal stability. The authors believed that compliance and stability were impaired after bladder neck reconstruction and that 25% of patients with exstrophy may maintain normal detrusor function after reconstruction. In an earlier paper by Hollowell et al. (1993), 13 of 21 children revealed involuntary contractions and only 4 revealed stable bladders before bladder neck reconstruction. Also, 7 of 21 had increased pressures (greater than 10 cm H_2O), suggesting decreased compliance. The difference in findings between these 2 urodynamic studies is difficult to explain from an experimental perspective. However, standardized methods of bladder neck repair do not exist, and these differences may be reflected in the different urodynamic findings after bladder neck repair in these 2 groups of patients.

Several interesting aspects of the microstructure of the bladder in children with bladder exstrophy were noted by Mathews et al. (2004), who used specimens obtained from children with bladder exstrophy at various stages of reconstruction (newborn bladder closure, bladder neck reconstruction, augmentation cystoplasty). At the cellular level, important differences were noted. Caveolae, which are important intracellular structures involved in cell-cell signaling, were found to be normal in the patients with a successful closure and improvement in bladder capacity and significantly lacking in the patients who required eventual augmentation cystoplasty (Fig. 31.12). In addition, the ultrastructure of cells in the patients in whom closure failed was noted to be abnormal. In a study by Suson et al. (2012a), an attempt was made to further identify similarities and differences between exstrophy smooth muscle and normal bladder muscle. More than 95% of exstrophy and control smooth muscle cells stained positive for actin and myosin. The intracellular calcium has been shown to be significantly lower in smooth muscle cells of exstrophic bladders compared with vesicoureteral reflux controls. More exstrophy cells migrated than control cells, although it is not known if this movement is organized or directional. There were no differences in cell proliferation between the two groups. In a second study, Suson et al. (2012b) showed that enhanced exstrophy smooth muscle cell migration was a result of excess transforming growth factor-β1 signaling but was independent of increases in intracellular calcium concentration.

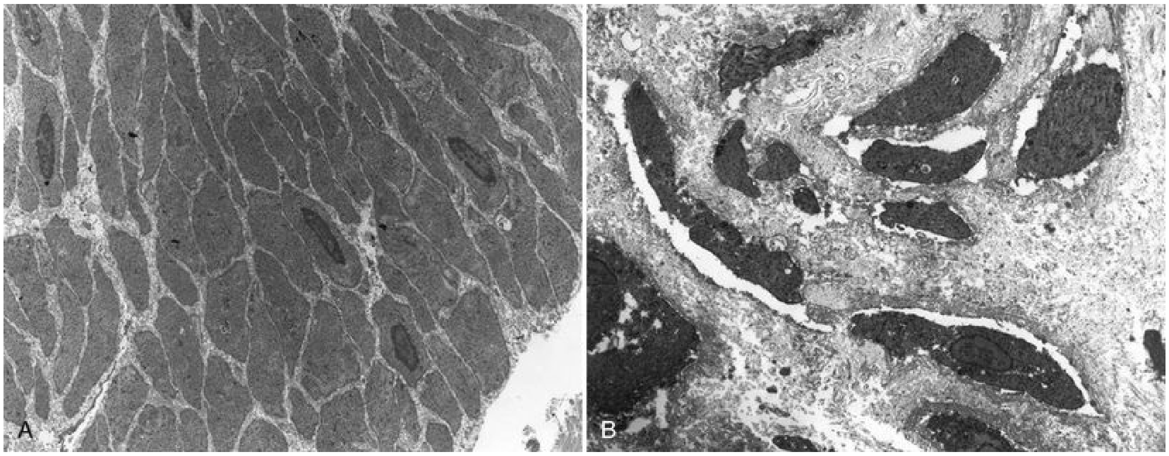

FIG. 31.12 Ultrastructural changes noted in the exstrophic bladder. (A) Normal muscle and nerve profiles in the newborn bladder. (B) After failure

of prior closure, significant deterioration is noted with increased intercellular collagen and degenerating muscle in an immunohistologic study. (From Mathews R, Gosling JA, Gearhart JP: Ultrastructure of the bladder in classic exstrophy: correlation with development of continence. *J Urol.* 172:1446–1449, 2004.)

The upper urinary tract is usually normal, but anomalous development does occur. In a recent report by Stec et al. (2012), 674 patients were reviewed; 462 were found to have had ultrasound examination. In this large review, 13 of 462 (2.8%) had a renal anomaly. The most common malformation was a duplicated collecting system (6); others included hypoplastic or absent kidney (3), pelvic kidney (2), ureteropelvic junction obstruction (1), and multicystic dysplastic kidney. This is a higher incidence than the 0.57% seen after 2 to 4 years of follow-up by antenatal screening (Rosendahl, 1990). The ureters have an abnormal course in their termination. The peritoneal pouch of Douglas between the bladder and the rectum is enlarged and unusually deep, forcing the ureter down laterally in its course across the true pelvis. The distal segment of the ureter approaches the bladder from a point inferior and lateral to the orifice, and it enters the bladder with little or no obliquity. **Therefore reflux in the closed exstrophy bladder occurs in 100% of patients, and reimplantation surgery is required at bladder neck reconstruction. If excessive outlet resistance is gained at the time of either initial closure or combined epispadias and bladder exstrophy closure, and recurrent infections may be a problem even with suppressive antibiotics. Ureteral reimplantation and/or revision of the outlet may be required before bladder neck reconstruction.** Ultimately, a successful staged reconstruction with bladder neck repair does not appear to adversely affect renal function (Schaeffer et al., 2013).

Exstrophy Complex and Variants

In addition to the three main presentations of the bladder exstrophy-epispadias complex—CBE, cloacal exstrophy, epispadias—many variations in anatomy and types of defects have been noted. Because there is probably a common embryologic origin for all of these defects, they all share many or some of the defects noted in the three major components of the complex—skeletal, urinary, and genital. The presence of a characteristic musculoskeletal defect of the exstrophy anomaly with no major defect in the urinary tract has been named *pseudoexstrophy* (Marshall and Muecke, 1968). Predominant characteristics include an elongated, low-set umbilicus and divergent rectus muscles that attach to the separated pubic bones. In this variant, the mesodermal migration has been interrupted in its superior aspect only, thus wedging apart the musculoskeletal elements of the infraumbilical abdominal wall.

In the superior vesical fissure variant of the exstrophy complex, the musculature and skeletal defects are exactly the same as those in classic exstrophy; however, the persistent cloacal membrane ruptures only at the uppermost portion, and a superior vesical fistula results that actually resembles a vesicostomy. Bladder extrusion is minimal and is present only over the normal umbilicus (see Fig. 31.1B).

In a large review of an exstrophy database of more than 815 patients, Lowentritt et al. (2005) **reported 25 exstrophy complex variants, of which six were cloacal exstrophy variants. Continence rates after bladder neck repair were compatible with classic exstrophy.** Three cases were reported by Arap and Giron (1986) in which the patients had classic musculoskeletal defects, and two of the three were continent. Of the two male patients, one had an associated complete epispadias and the other had a completely normal penis. Therefore the external genital manifestations in exstrophy variants can vary.

In addition to pseudoexstrophy, superior vesical fissure, and duplicated exstrophy, isolated occurrences of a fourth entity, covered exstrophy, have been reported (Cerniglia et al., 1989). This has also been referred to as *split symphysis variant.* A common factor in these patients is the presence of musculoskeletal defect associated with classic exstrophy but no significant defect of the urinary tract. Chandra et al. (1999) reported a covered exstrophy with incomplete duplication of the bladder. However, in cases of covered exstrophy (Cerniglia et al., 1989; Narasimharao et al., 1985), there has been an isolated ectopic bowel segment present on the inferior abdominal wall near the genital area, which can be either colon or ileum with no connection with the underlying gastrointestinal tract and only epispadias in the male. A patient seen at our institution had the standard appearance of most split symphysis variants, and the bladder could actually be seen through a thin membrane of lower abdominal skin (Fig. 31.13); all of the classic musculoskeletal defects of exstrophy were present. These patients should all undergo formal exstrophy closure at birth.

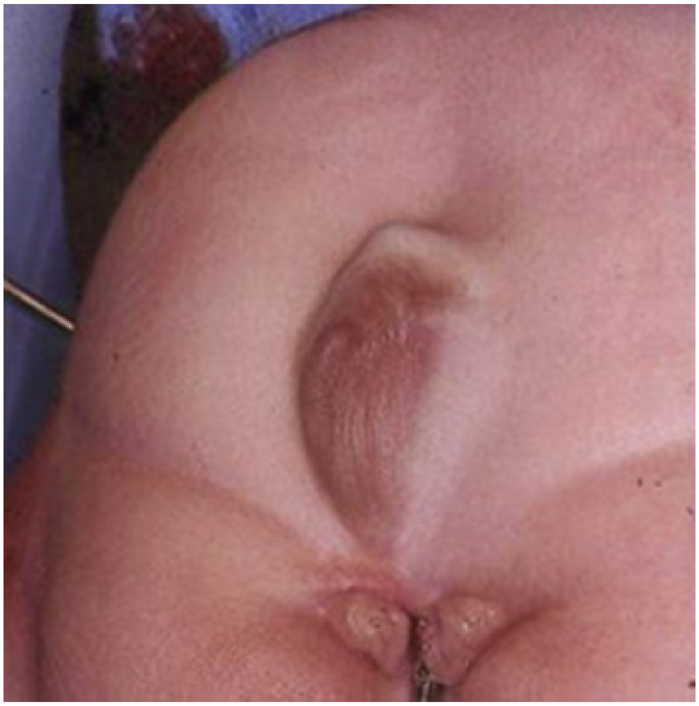

FIG. 31.13 Skin-covered exstrophy in a female patient. Note urethral sound in the bladder and the subcutaneous position below the skin of the abdominal wall. No bowel is sequestered on the abdominal wall, as has been reported in some patients with this variant.

There are two different forms of bladder duplication: anteroposterior duplication and side-by-side duplication. Anteroposterior duplication is considered a duplicate exstrophy with a patch of everted bladder mucosa on the anterior abdominal wall and a second bladder lying in the pelvis. The ureters attach to the closed bladder, rendering the superficial mucosa dry. The mainstay of treatment has been resection of the ectopic mucosa and closure of the abdominal wall defect. Side-by-side duplication involves patients who have two separately formed bladder halves in a left-right orientation with a midline septum between the bladders containing muscle. Each bladder has its own ureter and an intact sphincter. Often there is diastasis of the pubis and rectus muscle.

The bladder exstrophy–epispadias–cloacal exstrophy complex has a wide range of presentations. Variants are rare, but it is important to recognize the different appearances at birth, because the initial treatment will greatly influence the long-term outcome. Two patient groups had better outcomes than those with classic presentations—superior vesical fissure and skin-covered cloacal exstrophy. Because the sphincter is intact, patients with superior vesical fissure went through regular toilet training and became continent without the need for a later bladder neck procedure. Many reports of exstrophy variants include these patients, leading to the wrong belief that all patients with variants perform better than those with bladder exstrophy. Lowentritt et al. (2005) suggest that other than superior vesical fissure, all variants should be managed with formal exstrophy closure at birth and followed in the same manner as their classic presentations.

Prenatal Diagnosis

Even with modern ultrasound modalities, the prenatal diagnosis of bladder exstrophy is often difficult to delineate. Frequently, a diagnosis of omphalocele or gastroschisis is made and the exstrophy condition is overlooked. Ultrasound evaluation of the fetus by means of high-resolution real-time units allows a thorough survey of the fetal anatomy, even during routine obstetric ultrasound examinations (Gearhart et al., 1995a). Several groups have outlined important criteria for the diagnosis of CBE prenatally. In these reviews, the absence of a normal fluid-filled bladder on repeated examinations suggested the diagnosis, as did a mass of echogenic tissue on the lower abdominal wall (Mirk et al., 1986; Verco et al., 1986). An umbilical cord insertion-to-genital tubercle below the fifth percentile for gestational age also provides a quantitative measurement by which an exstrophy diagnosis can be assessed (Fishel-Bartal et al., 2017). **In a review of 25 prenatal ultrasound examinations with the subsequent birth of a newborn with CBE, Gearhart et al.** (1995a) **made several observations: (1) absence of bladder filling, (2) a low-set umbilicus, (3) widening pubis ramus, (4) diminutive genitalia, and (5) a lower abdominal mass that increased in size as the pregnancy progressed and as the intra-abdominal viscera increased in size** (Fig. 31.14).

FIG. 31.14 Prenatal ultrasound scan demonstrating bladder exstrophy. (A) Longitudinal view showing the low-set umbilicus (*cyan arrow,* lack of intra-abdominal bladder, and lower abdominal mass *(red arrow)*. (B) Transverse view through the plane *(X)* in A shows presence of the umbilicus *(cyan arrow)* and the upper edge of the bladder plate that appears hyperechoic *(red arrow).*

The application of 3D ultrasonography and fetal MRI has only somewhat improved the antenatal diagnosis of bladder and cloacal exstrophy, because only 25% of cases of bladder exstrophy-epispadias complex are diagnosed prenatally (Goyal et al., 2012). In our practice, fetal MRI is reserved for patients in whom 3D ultrasonography is not sufficient to differentiate satisfactorily between classic and cloacal exstrophy, or when other severe anomalies are suspected. With the increased granularity of MRI, this imaging modality may be used to exclude cloacal exstrophy or associated spinal anomalies (Goldman et al., 2013). The main reason for the prenatal diagnosis of bladder exstrophy is so that the parents can be counseled regarding the risks and benefits and other aspects of the condition. After appropriate counseling, arrangements can be made for delivery of the baby in a specialized exstrophy center where immediate reconstruction of the exstrophy can occur. Delivery in a specialized exstrophy center allows the parents to be exposed to the expertise of multiple disciplines, including the all-important psychological support these parents need when a child with a birth defect of this magnitude is delivered.

Key Points: Prenatal Diagnosis

Diagnostic criteria for CBE on ultrasound include

- Absence of bladder filling
- Low-set umbilicus
- Widening pubic rami
- Diminutive genitalia
- Lower abdominal mass that increases in size as the pregnancy progresses

Surgical Reconstruction of Bladder Exstrophy

Sweetser et al. (1952) initially described a staged surgical approach for bladder exstrophy. From 4 to 6 days before bladder closure, bilateral iliac osteotomies were performed. Epispadias repair was performed as a separate procedure. The continence procedure was limited to freeing the fibers from the intrasymphyseal band and wrapping this band around the urethra at the time of closure to increase outlet resistance.

The initial staged approach to functional bladder closure included three separate stages: bladder and abdominal wall closure; bladder neck reconstruction and antireflux procedure; and later epispadias repair. This approach was recommended for most cases of exstrophy reconstruction beginning in the early 1970s (Cendron, 1971; Jeffs et al., 1972; Williams and Keaton, 1973). **Although this procedure was successful, it has been modernized in the last 15 years to include bladder closure, abdominal wall closure, and posterior urethral closure well onto the shaft of the penis in the newborn period with bilateral innominate and vertical iliac osteotomy, if indicated; epispadias repair at 6 months to 1 year of age; and bladder neck reconstruction along with antireflux procedure at age 5 to 7 years, when the child has achieved an adequate bladder capacity for bladder neck reconstruction and/or when the child is motivated to participate in a postoperative voiding program** (Gearhart and Jeffs, 1998).

Other methods of treatment of the newborn with bladder exstrophy have been offered. Grady and Mitchell (1999) proposed combining bladder exstrophy closure with penile repair in the newborn period. Kelly (1995) has recommended a staged repair in which no osteotomy is used and a second-stage “radical soft-tissue mobilization” is performed before later urethral repair. Schrott et al. (1984) recommended bladder closure, ureteral reimplantation, epispadias repair, and bladder neck reconstruction in the newborn period. Last, Stein et al. (1999) recommended ureterosigmoidostomy in the newborn period with abdominal wall and bladder closure.

Evaluation and Management at Birth

At birth, although the bladder mucosa is usually smooth, pink, and intact, it is also sensitive and easily denuded. In the delivery room the umbilical cord should be tied with 2-0 silk close to the abdominal wall so that the umbilical clamp does not traumatize the delicate mucosa and cause excoriation of the bladder surface. The bladder can then be covered with a nonadherent film of plastic wrap (e.g., Saran Wrap) (Fig. 31.15) to prevent sticking of the bladder mucosa to clothing or diapers. In addition, each time the diaper is changed the wrap should be removed, the entire bladder surface irrigated with sterile saline, and clean plastic wrap placed over the bladder surface area.

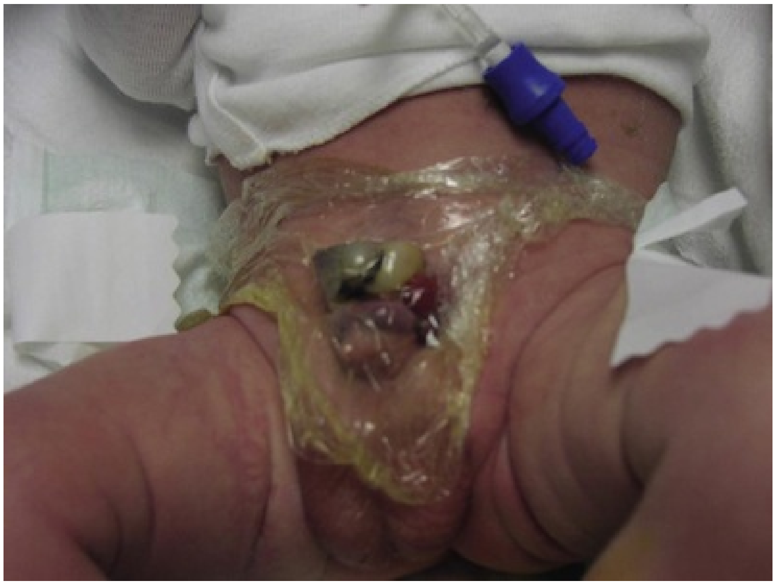

FIG. 31.15 Use of plastic wrap to keep bladder plate moist before closure.

The parents typically need reassurance at this stage. Counseling of the parents and decisions regarding eventual therapy should begin prenatally if the condition is diagnosed by prenatal ultrasonography. The parents should be educated by a surgeon with a special interest and experience in managing the exstrophy spectrum. An exstrophy support team should be available and should include a pediatric orthopedic surgeon, pediatric anesthesiologist, social workers, nurses with special interest in bladder exstrophy, and a child psychiatrist or psychologist with expertise and experience in genital anomalies. The Association for the Bladder Exstrophy Community is available and has a website for parents and family members to obtain further information about the bladder exstrophy condition.

Cardiopulmonary and general physical assessment measures can be carried out in the first few hours of life. Well-done ultrasound studies are usually sufficient to provide evidence of renal structure, function, and drainage, even in the first few hours of life before the patient undergoes closure of the exstrophy defect.

Circumstances may be less than ideal at birth. A thorough neonatal assessment may have to be deferred until transportation to a major children's medical center can be arranged. With modern transportation, no child is ever more than a few hours away from a neonatal center with full diagnostic and consultative services. During travel the bladder should be protected by a plastic membrane, as in the nursery, to prevent damage to the delicate newborn bladder mucosa.

Key Points: Bladder Exstrophy: Evaluation of the Newborn

- When evaluating a newborn with bladder exstrophy, a detailed exam must be performed:
    - Evaluate the size and quality (which includes polyp burden) of the bladder template. A suitable size for closure during the newborn period is 3 x 3cm.
    - Evaluate the extent of pubic diastasis radiographically and the malleability of the pelvis with an examination under anesthesia.
    - Determine the need for osteotomy.
    - Examine the length and width of the urethral plate.
    - Examine the penile length.
    - Evaluate the patient for associated anomalies.

Selection of Patients for Immediate Closure

Successful treatment of exstrophy with functional closure demands that the potential for success in each child be carefully considered at birth by an experienced exstrophy surgeon. The size and the functional capacity of the detrusor muscle are important considerations for the eventual success of functional closure. Correlation between apparent bladder size and the potential bladder capacity must not be confused. In minor grades of exstrophy that approach the condition of complete epispadias with incontinence, the bladder may be small yet may demonstrate acceptable capacity, either by bulging when the baby cries or by indenting easily when touched by a sterile gloved finger in the operating room with the child under anesthesia. **Sometimes a good bit of previously unappreciated bladder can be discovered behind the fascia on examination with anesthesia** (Gearhart and Jeffs, 1998). Once the bladder is relieved of surface irritation and repeated trauma, the small bladder can enlarge and increase in capacity with the absence of sphincter activity and with minimal outlet resistance. If the infant is robust and has a good bladder template and an experienced exstrophy team is present, then a newborn closure should be strongly considered. From new basic science studies, expression of the protein uroplakin II, found on surface urothelial cells, appears to be significantly higher in bladder specimens from non-exstrophy controls and newborn closures when compared with specimens from delayed exstrophy closures (Kasprenski et al., 2018b). As such, urothelial markers of bladder differentiation show that early closure may potentiate bladder growth.

Small Exstrophy Bladder Unsuitable for Newborn Closure

A small, fibrotic bladder patch that is stretched between the edges of the small triangular fascial defect without elasticity or contractility cannot be selected for the usual closure procedure (Gearhart and Jeffs, 1998) (see Fig. 31.11A). Examination with the patient under anesthesia is often required to assess the bladder adequately, particularly if considerable edema, excoriation, and polyp formation have developed between birth and the time of assessment. **Decisions regarding the suitability of bladder closure or the need for waiting should be made only by surgeons with a great deal of experience in the exstrophy condition** (Gearhart and Jeffs, 1998). Some conditions preclude primary closure, including penoscrotal duplication, ectopic bowel within the extruded bladder (a relative contraindication), a hypoplastic bladder, and significant bilateral hydronephrosis.

In a study of delayed primary closures by Baradaran et al. (2012a), the bladder growth of those delayed because of small bladder templates was compared with those whose closure was delayed secondary to late referral to the institution. Thirty-two (97%) of the 33 patients underwent pelvic osteotomy. Those delayed for small bladder templates tended to be older at the age of primary closure (305 days vs. 172 days). Overall, the mean bladder capacity of patients in the small bladder template group was 36 mL smaller than the bladder capacities of those undergoing neonatal closure (95% CI −65 to −10). In those whose primary closure was delayed because of late referral, the bladder capacities were 29 mL less than neonatal closures (95% CI −60 to 5). Although the measured bladder capacities were smaller in the patients with a delayed primary closure, notably, the annual growth is similar (Baradaran et al., 2012a).

Thus waiting for the bladder template to grow for 6 to 12 months in the child with a small bladder is not as risky as submitting a small bladder template to closure in an inappropriate setting, resulting in dehiscence and possible future incontinence. Ultimately, delaying the primary closure when indicated does not jeopardize the growth of the bladder (Baradaran et al., 2012a; Ferrara et al., 2014). If the bladder does not grow to sufficient size for closure after 6 to 12 months, other options include excision of the bladder and a nonrefluxing colon conduit or ureterosigmoidostomy.

Osteotomy

Children born with bladder exstrophy have not only an exposed bladder but also a wide diastasis of the pubic rami (average 4.8 cm), resulting in an open pelvic ring. In addition, the larger the bladder template, the wider the resultant diastasis and the greater the need for osteotomy. The musculoskeletal function of the hip and lower extremity appears to be normal throughout childhood; however, the gait is characterized by external foot rotation, which lessens with growth as lower extremity muscle function strengthens, even if osteotomy is not performed.

Several types of pelvic osteotomies have been developed to help to close the pelvic ring, decrease the stress on the abdominal wall during initial exstrophy closure, and improve the outcome of future genitourinary reconstruction. Pelvic osteotomies also provide the added benefit of decreased incidences of primary and recurrent inguinal hernias (Lavien et al., 2014). Shultz (1958) was the first, as far as we know, to describe bilateral posterior iliac osteotomy as part of a two-stage repair of bladder exstrophy. Bilateral posterior iliac osteotomy was performed, and 1 to 3 weeks later exstrophy closure was accomplished. This early osteotomy was shown to lower rates of wound dehiscence and to help achieve a more secure and better genitourinary reconstruction.

Patients may undergo pelvic osteotomy at any stage of exstrophy repair if the diastasis prevents attainment of these urologic goals. **In general, we do not routinely perform osteotomy on newborns unless the diastasis is over 4 cm or the malleability of the pelvis is poor as judged jointly by a senior pediatric urologist and pediatric orthopedic surgeon.** The rates of failed closures in newborn patients with osteotomy was found to be statistically similar to the rates of carefully selected newborns without osteotomy (6.5% vs. 10.5%, *P* = 0.466) (Inouye et al., 2016). The laxity of the sacroiliac ligaments usually allows closure of the defect without undue tension in the first 48 to 72 hours of age. We make this decision with the patient under anesthesia at the time of primary closure with our pediatric orthopedic colleagues.

Types of osteotomies that have been used include bilateral osteotomy of the superior pubic ramus, diagonal osteotomy of the iliac wing, and anterior innominate osteotomy with or without vertical iliac osteotomy. The more commonly used combined anterior innominate and vertical osteotomy was developed for several reasons: (1) the osteotomy is performed with the patient in the supine position as for the urologic repair, avoiding the need to turn the patient; (2) the anterior osteotomy also allows placement of an external fixator and intrafragmentary pins under direct vision; (3) a greenstick-type closing-wedge osteotomy of the ilium is also performed adjacent to the sacrum in most patients, creating two large bony fragments that are easily movable; (4) the cosmetic appearance of this osteotomy is superior to that of a posterior iliac osteotomy (Gearhart et al., 1996b); and (5) the superior pelvic bone malleability and ease of apposition of the pubic bone without tension.

After failure of initial closure in children with significant pubic diastasis, as seen in large bladder templates and cloacal exstrophy, osteotomy is always required. Pubic approximation may not be possible in a single step at the time of abdominal closure when the diastasis is extreme (>6 cm). The use of staged closure of the pelvis after osteotomy has been used successfully in this circumstance. This technique has been used for the treatment of children with extreme diastasis, even in younger patients, and the cloacal exstrophy condition.

Pelvic osteotomy performed at the time of initial closure confers several advantages, including (1) easy approximation of the symphysis with diminished tension on the abdominal wall closure and elimination of the need for fascial flaps; (2) placement of the posterior vesicourethral unit deep within the pelvic ring, enhancing bladder outlet resistance; and (3) bringing the large pelvic floor muscles near the midline, where they can support the bladder neck and aid in eventual urinary control (Fig. 31.16). After pubic approximation with osteotomy, some patients show the ability to stop and start the urinary stream, experience dry intervals, and in some cases become completely continent (Gearhart and Jeffs, 1991a). In a review of a large number of patients referred to our institution after failed exstrophy procedures, it was found that a majority of the patients who had partial or complete dehiscence of the bladder or major bladder prolapse had not undergone an osteotomy at the time of initial bladder closure (Gearhart et al., 1993b). We recommend performing bilateral transverse innominate and vertical iliac osteotomy when bladder closure is performed after 72 hours of age (Fig. 31.17). In addition, if the pelvis is not malleable or if the pubic bones are more than 4 cm apart at the time of initial examination under anesthesia, osteotomy should be performed, even if closure is done before 72 hours of age. A well-coordinated surgery and anesthesia team can perform osteotomy and proceed to bladder closure without undue loss of blood or risk of prolonged anesthesia in the child. However, osteotomy together with posterior urethral and bladder closure and abdominal wall closure is a 5- to 7-hour procedure in these infants.

FIG. 31.17 The technique of combined osteotomy showing bony incision sites and pin placement.

If the patient is younger than 72 hours old and examination under anesthesia reveals that the pubic bones are malleable and able to be brought together easily in the midline by medial rotation of the greater trochanters, the patient can undergo closure without osteotomy. No chances should be taken with a decision of this magnitude, and if any doubt exists, an osteotomy should be performed.

The most frequently used osteotomy today is the bilateral anterior innominate and vertical iliac osteotomy, popularized by Gearhart et al. in 1996 (Gearhart et al., 1996b). This approach improves the ease of symphyseal approximation in the patient with exstrophy compared with posterior approaches. In our experience, this osteotomy is superior to the pubic mobilization seen with simple bilateral transverse anterior innominate osteotomy or even pubic ramotomy. **With the ease of approximation obtained with this combined osteotomy, tension on the midline abdominal closure is lessened and the rates of bladder dehiscence and bladder prolapse are markedly decreased** (Gearhart and Jeffs, 1998). In addition, pelvic closure allows anterior movement of the levator ani to strengthen the puborectalis sling. This helps position the bladder neck and posterior urethra deep within the pelvic ring and improved continence rates. This also moves the pelvic floor muscles into a more anterior position, thus providing more support for the anterior pelvic organs.

Combined osteotomy is performed by placing the patient in the supine position, preparing and draping the lower body below the costal margins, and placing soft, absorbent gauze over the exposed bladder. The pelvis is exposed from the iliac wings inferiorly to the pectineal tubercle and posteriorly to the sacroiliac joints. The periosteum and sciatic notch are carefully elevated, and a Gigli saw is used to create a transverse innominate osteotomy exiting anteriorly at a point halfway between the anterior superior and anterior inferior spines (see Fig. 31.17). This osteotomy is created at a slightly more cranial level than that described for a Salter osteotomy to allow placement of external fixator pins in the distal segments. In addition to the transverse osteotomy, the posterior ileum may be incised from the anterior approach in an effort to correct the deformity more completely. For this part of the osteotomy, an osteotome is used to create a closing wedge osteotomy vertically and just lateral to the sacroiliac joints. The proximal posterior iliac cortex is left intact and used as a hinge (see Fig. 31.17). This combination osteotomy easily corrects the abnormalities in the anterior and posterior segments of the pelvis.

Two fixator pins are placed in the inferior osteotomized segment, and two are placed in the wing of the ileum superiorly. Radiographs are obtained to confirm pin placement, soft tissues are closed, and the urologic procedure is performed (see Fig. 31.16). At the end of the procedure, the pelvis is closed with a suture between the two pubic rami. The external fixators are then applied between the pins to hold the pelvis in a correct position. In a newborn with less than optimal amounts of cancellous bone, only one pin is placed inferiorly and superiorly in the wing of the ileum, instead of two as in older children.

Radiographs are taken 7 to 10 days after surgery to look for complete reduction of the symphyseal diastasis. If this diastasis has not been completely reduced, the right and left sides can be gradually approximated by means of the fixator bars over several days. Longitudinal skin traction is used to keep the legs still (Fig. 31.18). The patient remains supine in traction for approximately 4 weeks to prevent dislodgement of tubes and destabilization of the pelvis. The external fixator is kept on for 4 to 6 weeks, until adequate callus is seen at the site of the osteotomy (see Figs. 31.16B and 31.17). Postoperatively, in newborns who undergo closure without osteotomy in the first 48 to 72 hours of life, the baby is immobilized in modified Bryant traction in a position in which the hips have 90 degrees of flexion. When modified Bryant traction is used, the traction is used for 4 weeks. A horizontal mattress suture of No. 2 nylon is placed between the fibrous cartilage of the pubic rami and tied anteriorly to the pubic closure at the time of bladder closure. **Evidence obtained by Sussman et al.** (1997) **from biomechanical testing in an intact piglet pelvic model revealed that all methods of pubic approximation were weak compared with the intact symphysis. However, the best technique with the strongest load-to-failure ratio was a No. 2 nylon horizontal mattress suture**.

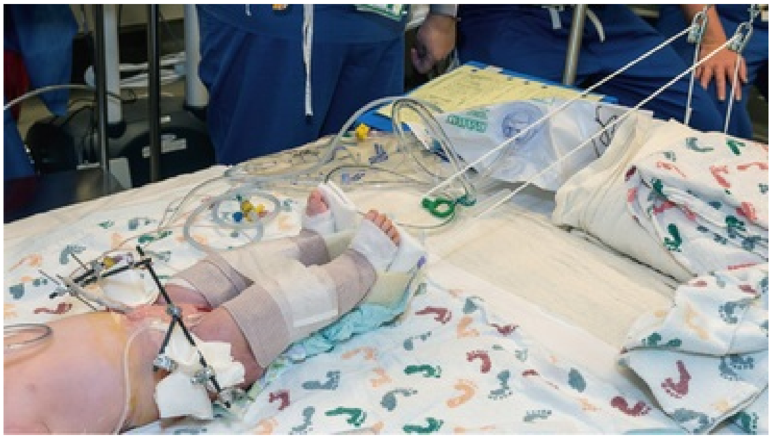

FIG. 31.18 Three-week-old patient after primary of bladder exstrophy with external fixator in place and modified Buck traction.

Complications of Osteotomy and Immobilization Techniques

Complications of inadequate immobilization can include failure of the closure, bladder prolapse, loss of suprapubic tubes, and ureteral stents. Closely related to inadequate immobilization is inadequate pain and movement control. With tunneled epidural catheters for 2 to 3 weeks, pain and movement are well controlled while the pelvic bone callus formation increases in the osteotomy wound and the wound stabilizes.

Some centers still prefer to use spica casts and mummy wraps. In a series from Seattle, the authors preferred spica casts with or without osteotomy over other techniques and felt this allowed earlier discharge from the hospital (Shnorhavorian et al., 2010). However, in a large series of 86 failed exstrophy closures, Meldrum et al. (2003) found that most had been immobilized with a mummy wrap or spica cast. Successful closure was noted in 97% of those immobilized with an external fixator and modified Buck traction. In our experience, we have seen a similar success rate in patients immobilized in such a manner during the primary closure. When patients with repeat closures were included, more than 92% of patients immobilized with longitudinal traction and external fixation were successfully closed. In contrast, however, we have seen that only 53% of patients immobilized with spica casts are successfully closed (Table 31.1). As such, we recommend longitudinal traction and external fixation, particularly in the setting of pelvic osteotomy, to ensure appropriate immobilization and stability of the pelvis (Baumgartner et al., 2017a). Recently, advocates of spica casts have begun to apply them for 8 weeks for better and safer immobilization.

TABLE 31.1

Pelvic Immobilization After the Closure of Classic Bladder Exstrophy

METHOD OF IMMOBILIZATION	TOTAL CLOSURES		CLOSURES WITH OSTEOTOMY		CLOSURES WITHOUT OSTEOTOMY	
	TOTAL NO. (N = 245)	NO. FAILED (%)	TOTAL NO. (N = 180)	NO. FAILED (%)	TOTAL NO. (N = 60)	NO. FAILED (%)
Spica cast	112	53 (47.3)	53	16 (30.2)	55	36 (65.5)
External fixation with traction	133	10 (7.5)	127	10 (7.9)	5	0
P-value		<0.005		<0.005		0.006

Modified from Baumgartner T, Jayman J, Friedlander D, et al.: The role of pelvic and lower limb immobilization in classic bladder exstrophy: an institutional study of three mainstay techniques. Pediatric Urology Fall Congress, Society for Pediatric Urology, Montreal, Canada, 2017.

Sponseller et al. (2001) reported on a total of 86 combined bilateral anterior innominate and vertical iliac osteotomies performed in 88 children. Of these, 10 children had cloacal exstrophy and 72 had bladder exstrophy with at least 2 years of clinical follow-up (mean 4.8 years). Complications included 7 cases of transient left femoral nerve palsy, which resolved fully by 12 weeks after surgery. There were no cases of right femoral nerve palsy, although the same surgeon performed the same technique on both sides. Patients with transient femoral nerve palsy were on bed rest for the first 6 to 8 weeks; a knee immobilizer was needed for the remaining 6 weeks until resolution. Other complications included 3 cases of delayed ileal union, 1 case of superficial infection of the ileal femoral incision that required irrigation and debridement, 1 case of transient right thigh abductor weakness, 1 infection of the ileum around a pin site requiring irrigation and debridement, and 1 case of transient right peroneal palsy. Almost all patients had skin inflammation around the pins, particularly those in the proximal (iliac crest) segments. This was always controlled with the use of oral antibiotics. In a paper by Satsuma et al. (2006), comparisons were made between patients who underwent posterior iliac or combined osteotomy. Pubic approximation was better and the mean recurrence far less in the combined transverse innominate and vertical iliac osteotomy. Thus the combined approach corrected and maintained the pelvic ring with fewer complications than a posterior pelvic osteotomy.

When good callus formation is seen on radiography, the fixating device and pins are removed at the bedside with the patient under light sedation. The age of the patient plays a role in the amount of correction of the diastasis that is maintained over time. On review of the previously described types of osteotomy, classic and cloacal exstrophy patients gained approximation, although the former group gained greater correction toward normal (Gearhart et al., 1996b). Greater preoperative diastasis as well as less optimal bone density in the newborn contributes to the greater difficulty in obtaining and maintaining closure of the pelvic bone deformity over time.

It is our impression that partial recurrence of diastasis occurs in classic exstrophy by two mechanisms, even after osteotomy. First, the pelvis may partially derotate because of early loosening of pins before the time of osteotomy healing; this is seen mostly in infants. In the older child, increased bone density allows more rigid external fixation and thus better maintenance of the corrected position. Second, there is long-term undergrowth of the ischiopubic segment, which has been shown to be 33% smaller than normal in the adult with exstrophy, as the pelvis grows. Pubic diastasis increases with growth in the patient with uncorrected exstrophy. Therefore, even with some loss of approximation, significant correction remains in comparison with the unoperated state. **We regard the main role of osteotomy to be relaxation of tension on the bladder, posterior urethra, and abdominal wall repair during healing.** Therefore we use osteotomy less in newborns and young infants because ligament laxity allows the pelvis to be closed without tension if the diastasis is reasonable and pubic bones are malleable. However, it becomes essential in the older child with a failed exstrophy repair, in the patient with cloacal exstrophy, and in a newborn with a wide diastasis and excellent bladder template. In patients undergoing combined exstrophy closure and epispadias repair, osteotomy allows the pubis to be joined, making it easier for the corpora to be brought over the closed proximal urethra (Gearhart et al., 1998). In a large series of failed exstrophy reclosures (mean age 23.2 months), 56 patients were found who underwent repeat pelvic osteotomy (Nelson et al., 2006). All of the reclosures were successful, and 95% of the patients had a normal gait after reoperative osteotomy. There were no femoral or sciatic nerve palsies, and only five local pin site infections, which were easily treated. Repeat pelvic osteotomy is safe with few complications in experienced hands.

Whichever type of osteotomy is used, pelvic ring closure not only allows midline approximation of the abdominal wall structures but also allows the levator ani and puborectalis muscles to lend potential support to the bladder outlet, thus increasing resistance to urinary outflow (see Fig. 31.16D) (Gearhart et al., 1993b, 1996b; McKenna et al., 1994; Schmidt et al., 1993; Sponseller et al., 1991). Furthermore, a continence procedure can be performed later on the bladder neck and urethra deep within the closed pelvic ring at a distance from the surface without independent movement of the two halves of the pubis. The urethra and bladder neck are set more deeply in the true pelvis, in a more normal relationship than when acutely angulated.

Although the use of osteotomy during initial closure has significantly increased success rates, failures can still occur even with the use of osteotomy. Sirisreetreerux et al. (2017) looked at a large group (n = 156) of exstrophy patients closed with an osteotomy, of which 30% failed their primary closure. Using multivariate analysis, the authors found that the use of Buck's traction and external fixation with an immobilization time greater than 4 weeks significantly lowered the risk of failure. Although osteotomy performed by general, not pediatric, orthopedic surgeons had significantly higher odds of failure. Interestingly, the type of osteotomy and the use of epidural anesthesia did not significantly impact failure rates. Thus osteotomy is a valuable adjunct to both primary and secondary exstrophy closure, but failures can still occur (Sirisreetreerux et al., 2017).

Immobilization Techniques

- Mummy wrap
- Spica casts

- Modified Bryant's traction (only when osteotomy is not performed)
- Modified Buck's traction (used in combination with external fixator device)
- External fixator device

Surgical Options in the Newborn With Classic Bladder Exstrophy

Regardless of which reconstructive method is used, the surgical correction of bladder exstrophy actually begins with preoperative anesthetic management. This frequently involves a combination of general and epidural anesthesia. Epidural catheters are advanced between 6 cm and 10 cm through the insertion needle to reach the T10-12 thoracic dermatome (Kost-Byerly et al., 2008). This is initially injected with a fractionated dose of 1 mL/kg of 0.25% (2.5 mg/mL) bupivacaine with 1 : 200,000 epinephrine (5 mcg/mL), using electrocardiography to monitor for intramuscular injection. Intraoperatively, the catheter is reinjected in 2-hour intervals with 0.6 mL/kg of 0.25% bupivacaine with 1 : 200,000 epinephrine or a 1 mL/kg 0.125% (1.25 mg/mL) solution of bupivacaine with 1 : 200,000 epinephrine for the duration of the procedure.

Although modern staged repair of exstrophy (MSRE) currently enjoys widespread popularity, other methods have been described for the primary reconstruction of exstrophy and are used in good centers. This section discusses the other types of repair and their use and application. The outcomes and complications are discussed in separate sections; many are similar and their correction the same.

Kelly Repair

The radical soft-tissue mobilization procedure was developed by Kelly in the late 1980s and early 1990s as a means to improve on the technique described by Ansell (1983) and to obviate pelvic osteotomies that were often required to obtain a tension-free closure (Ansell, 1983). It is a multistage repair that includes (1) closure of the bladder dome and hernia repair at birth, followed at age 3 to 6 months by (2) reconstruction of the proximal urethra with associated sphincteric tissue with penile lengthening and creation of a penoscrotal urethrostomy in boys, and (3) repair of the resulting penoscrotal hypospadias at around 3 years of age. The unique aspects relate to the second stage, in which a more radical mobilization of the pelvic floor muscles is performed (Kelly, 1995). Specifically, the dissection includes the periosteum of the ischium and pubis, where the attachment of the voluntary and involuntary sphincter muscles, as well as the pudendal nerves and vessels, are found. The muscles are then wrapped around the reconstructed proximal urethra in an attempt to provide a continence mechanism. The neourethra is constructed from the urethral plate on the dorsum of the penis after it is dissected from the corporeal bodies much as in the penile disassembly technique. However, unlike the penile disassembly technique, the meatus is always brought to the penoscrotal junction and later is brought distally.

Complete Repair: Complete Primary Repair of Exstrophy

Developed by Mitchell, the complete repair combines the standard bladder closure with the “penile disassembly” technique for epispadias repair in an effort to decrease the number of procedures required for reconstruction and to provide continence without the need for formal bladder neck reconstruction (Grady and Mitchell, 1999).

This technique of penile repair was developed by Mitchell and Bägli (1996). It has now been incorporated in the complete primary repair of exstrophy (CPRE) for primary closure in the newborn.

The penis is dissected into three components—the right and left corpora with their associated hemiglans and the urethral wedge (urethral plate with its associated spongiosa) (Fig. 31.19). The dissection as in the Cantwell-Ransley repair begins on the ventral aspect of the penis. The dissection moves medially just above the Buck fascia but is taken down to the tunica albuginea of the corpora. Care is taken to preserve the spongiosum with the urethral wedge, and this dissection is carried posteriorly to the area of the bladder neck. The penis was formerly separated into the three aforementioned components. However, recently because of soft tissue loss, proponents have begun leaving the plate attached to the glans, with the repair resembling a modified Cantwell-Ransley repair (Borer et al., 2017). In a recent study by Kasprenski et al., 22 patients who underwent CPRE with complete penile disassembly were found to have soft-tissue loss (Kasprenski et al., 2018a). If the surgeon feels the urethral plate should be detached from the glans, the urethra is brought between the corpora to a hypospadiac position. The corpora are then positioned in the midline with interrupted sutures. Skin closure is similar to that of standard hypospadias repair with fine absorbable sutures. If concomitant exstrophy closure is to be done, the dissection then moves proximally into the pelvis to be able to move the structures into the pelvis. Another part of the complete repair is bladder neck “tailoring” to provide some outlet resistance after closure in the newborn (see Fig. 31.19).

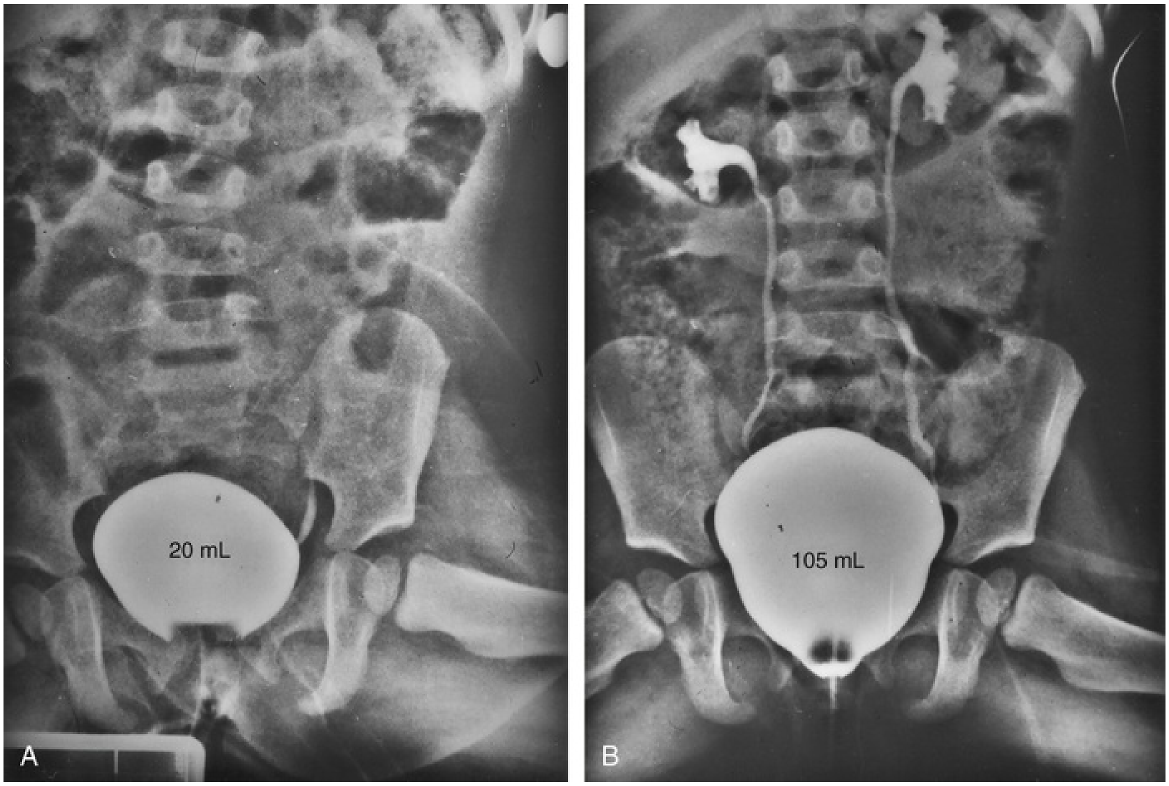

FIG. 31.19 (A) Initial cystogram under anesthesia showing small bladder capacity after bladder closure. (B) Improvement in bladder capacity noted after urethroplasty.

Mitchell emphasizes the importance of dissecting the perineal membrane from the pubis, allowing the bladder and posterior urethra to be set deep into the pelvis. This feature, however, is common to all properly performed exstrophy reconstructions and helps ensure success. The dissection of the urethral plate from the corpora leaves 60% to 75% of patients with hypospadias (Hafez and El-Sherbiny, 2005), and 50% of children require ureteral reimplantation in the first year of life (Grady and Mitchell, 1999).

Schrott-Erlangen Approach

The Erlangen approach is clearly the most evolved of any of the primary closure techniques. In the Erlangen approach, developed by Schrott and popularized by Rosch, if the bladder template is deemed of adequate size, the “total” repair is done at 8 weeks of age. If the template is too small at birth, the bladder only is closed with bilateral groin exploration, closure of the pubis, epispadias repair, and no osteotomy. In the classic Erlangen total repair, the bladder is closed along with bilateral reimplantations, bladder neck plasty, bilateral groin exploration, epispadias repair, pubic closure, no osteotomy, and an epidural catheter for 5 days. Osteotomy is only done in cloacal exstrophy and reoperative closures. Thus the Erlangen repair is truly a complete repair, encompassing all phases of exstrophy repair in one setting (Schrott et al., 1984). A long-term follow-up study of nearly 20 years found that 10 of 16 patients were objectively continent of urine and that most had normal renal function (Ebert et al., 2010).

Mainz Repair

Hohenfelner et al. first began using ureterosigmoidostomy for failed exstrophy patients and for patients with small bladder templates, which led to its use as a technique in primary exstrophy closures. Beginning in 1964, this was begun in all newborns with exstrophy, irrespective of bladder template size at birth. At the age of 2 years, the patient undergoes ureterosigmoidostomy. Some of the remnant bladder is made into a small seminal receptaculum, and the penis is reconstructed during the same procedure. In girls, the external genitalia are reconstructed and anterior fixation of the uterus is performed. In boys and girls, cosmetic correction is usually needed later. However, this usually means only one further operation. In 1996 Fisch et al. reported long-term results with the Mainz Sigma pouch (Fisch et al., 1996). This was designed to reduce intracolonic pressures and to maintain better fecal continence. Most of the patients are immediately started on oral alkalinization.

Regardless of the method of exstrophy reconstruction chosen for the newborn, certain surgical principles remain: (1) radical mobilization of the posterior vesicourethral unit from surrounding tissue; (2) combined closure with epispadias repair in only very carefully selected patients; (3) tension-free closure of the abdominal wall and pelvic bones with adjunctive osteotomy if needed; and (4) definition of strict criteria for selection of newborns to undergo closure.

Modern Staged Reconstruction of Bladder Exstrophy

The primary objective in functional closure is to convert the bladder exstrophy into a complete epispadias with the urethra well up onto the proximal shaft or midshaft of the penis with combined complete epispadias repair in only highly select patients. The resultant incontinence with balanced posterior outlet resistance not only preserves renal function but also stimulates bladder growth. Typically, epispadias repair is now performed at around 6 months of age, after testosterone stimulation. Bladder neck repair usually occurs when the child is 4 to 5 years of age, has an adequate bladder capacity, and, most important, is ready to participate in a postoperative voiding program. Many repairs such as the Erlangen, Kelly, and CPRE were purported to establish continence without the need for bladder neck repair, but recent reports have shown the need for an outlet procedure in almost all patients (Gargollo et al., 2011; Gearhart et al., 2005, 2007; Shoukry et al., 2009).

Bladder, Posterior Urethral, and Abdominal Wall Closure

Various steps in primary bladder closure are illustrated in Fig. 31.20A to H. A strip of mucosa 2 cm wide, extending from the distal trigone to well below the verumontanum up to the midshaft of the penis in the male and to the level of the vaginal orifice in the female, is outlined for prostatic and posterior urethral reconstruction in the male and adequate urethral closure in the female. The male urethral groove may be adequate, in which case no transverse incision of the urethral plate must be performed for urethral lengthening (see Fig. 31.20A). We tend not to incise a urethral plate unless the length of the urethral groove from the verumontanum to the urethral glans is so short that it interferes with eventual penile length and produces dorsal angulation. If so, the urethral groove is lengthened after the manner of Johnston (1974) or Duckett (1977). The drawings in Figs. 31.20B and C show marking of the incision just above the umbilicus, down the junction of the bladder and paraexstrophy skin, to the level of the urethral plate.

diaphragm fibers. Note stents and suprapubic tubes in place in the bladder. (G) Initial layer of the bladder closure. Urethral meatus is calibrated to 14-Fr size. Stents are brought out of the bladder. (H) Pubic approximation is performed with No. 2 nylon mattress suture *(see inset).* Abdominal wall closure is completed. Suprapubic tube and stents are brought out through the neoumbilicus. (Copyright Brady Urological Institute.)

An appropriate plane is entered just above the umbilicus, and a plane is established between the rectus fascia and the bladder (Fig. 31.20D). The umbilical vessels are doubly ligated and incised and allowed to fall into the pelvis. The peritoneum is taken off the dome of the bladder at this point so that the bladder can be placed deep into the pelvis at the time of closure. The plane is continued caudally down between the bladder and rectus fascia until the urogenital diaphragm fibers are encountered bilaterally. The pubis is encountered at this junction, and a double-pronged skin hook can be inserted into the bone at this time and pulled laterally to accentuate the urogenital diaphragm fibers and help the surgeon radically incise these fibers between the bladder neck, posterior urethra, and pubic bone (Fig. 31.20E). Gentle traction on the glans at this point shows the insertion of the corporeal body on the lateral inferior aspect of the pubis. These urogenital diaphragm fibers are taken down sharply with electrocautery down to the levator hiatus in the pelvic floor in their entirety (Fig. 31.20F). If this maneuver is not performed adequately, the posterior urethra and bladder will not be placed deeply into the pelvis, and when the pubic bones are brought together, the posterior vesicourethral unit will be brought anteriorly into an unsatisfactory position for later Cantwell-Ransley epispadias repair. Di Carlo et al. have recently shown the advantage of using 3D MRI–guided dissection of the pelvic diaphragm to enhance the accuracy and safety of this dissection (Fig. 31.21) (Di Carlo et al., 2017). If the urethral plate is left in continuity, it must be mobilized up to the level of the prostate to create as much additional urethral and penile length as possible. Further urethral lengthening can be performed at the time of epispadias repair.

FIG. 31.21 Intraoperative image-guided exstrophy repair with preoperative magnetic resonance imaging (MRI) is performed with Brainlab. During the closure, the surgeon identifies the urogenital muscle fibers and the smooth and striated muscle fibers of the posterior urethra and bladder plate *(left).* These structures are verified with a three-dimensional reconstruction of a triplanar MRI *(right).*

Penile lengthening is achieved by exposing the corpora cavernosa bilaterally and freeing the corpora from their attachments to the suspensory ligaments on the anterior part of the inferior pubic rami. **However, because Silver et al.** (1997b) **showed that there is a 50% shortage of length of the corporeal bodies in exstrophy versus normal controls, any penile length that is obtained is through correction of chordee and change in angulation of the penis rather than true penile lengthening.** The wide band of fibers and muscular tissue representing the urogenital diaphragm is detached subperiosteally from the pubis bilaterally (Fig. 31.20E). Reluctance to free the bladder neck and urethra well from the inferior ramus of the pubis moves the neobladder opening cephalad should any separation of the pubis occur during healing, thus increasing the chance of bladder prolapse. The mucosa and muscle of the bladder, bladder neck, and urethra are then easily closed well onto the mid-shaft of the penis in the midline anteriorly (Fig. 31.20G). This posterior vesicourethral unit should be “tapered” over a 12-Fr sound. The purpose of this tapering is to slightly narrow and elongate this unit to allow it to be placed deeply into the pelvis. The size of the opening should allow enough resistance to aid in bladder adaptation and to prevent prolapse but not enough outlet resistance to cause upper tract changes. This area will be the site of future bladder neck reconstruction. The posterior urethra and bladder neck are buttressed with a second layer of local tissue if possible. The bladder is drained by a suprapubic nonlatex Malecot catheter for a period of 4 weeks. The urethra is not stented to avoid necrosis with accumulation of secretions in the neourethra. Stents provide drainage during the first 10 to 14 days after closure, because swelling caused by the pressure of closure of a small bladder can obstruct the ureters and give rise to obstruction and transient hypertension. If there are no problems with the stents during healing, we leave the stents in for as long as 2 to 3 weeks.

When the bladder and urethra have been closed and the drainage tubes placed, pressure over the greater trochanters bilaterally allows the pubic bones to be approximated easily in the midline. Horizontal mattress sutures are placed in the pubis and tied with a knot away from the neourethra (Fig. 31.20H). Often we are able to use another stitch of No. 2 nylon at the most caudal insertion of the rectus fascia onto the dorsal pubic bone. This maneuver adds to the security of the pubic closure. A V-shaped flap of abdominal skin at a point corresponding to the normal position of the umbilicus is tacked down to the abdominal fascia, and a drainage tube exits this orifice. The method described by Hanna (1986) is our most commonly performed procedure. Before and during the procedure, the patient is given broad-spectrum antibiotics in an attempt to convert a contaminated field into a clean surgical wound.

For the very short penis at birth, the urethral groove must be transected. As described by Duckett (1977), the groove is then cut distal to the verumontanum with continuity maintained between the thin, mucosal, paraexstrophy non–hair-bearing skin adjacent to the posterior urethra and bladder neck and the skin and mucosa of the penile skin and glans. Flaps in the area of the thin skin are subsequently moved distally and rotated to reconstruct the urethral groove, resurfacing the penis dorsally. The corporeal bodies are not brought together at this juncture because later Cantwell-Ransley repair is planned.

Combined Bladder Closure and Epispadias Repair

MSRE has yielded consistently good cosmetic and functional results, and the use of osteotomy has improved the potential for successful initial closure and later continence. **In an effort to decrease costs, decrease the morbidity associated with multiple operative procedures, and possibly affect continence, there has been interest in performing single-stage reconstruction or combining**

procedures in appropriately selected patients. This technique was first described by Lattimer and Smith (1966) but was abandoned in the 1970s because of high complication and failure rates. The technique was revisited by Gearhart and Jeffs (1991a) for failed exstrophy closures and more recently by Grady and Mitchell for newborn patients (1999). In the combined exstrophy and epispadias repair, bladder closure is combined with the modified Cantwell-Ransley epispadias repair (Baird et al., 2005c; Gearhart and Mathews, 2000). This technique can be applied to delayed primary closure and failed closures. This method does not require making the patient hypospadiac.

Results have now emerged in groups of boys undergoing single-stage reconstruction (bladder closure and epispadias repair) in infancy (Baird et al., 2005c; Gearhart et al., 1998). In our opinion, this technique should be limited to boys of older age (older than 6 months) because of evidence indicating that potential complication of these combined procedures is significant loss of penile and corporeal tissue that makes further reconstruction problematic (Cervellione et al., 2010). Patients should be carefully selected, and use of these extensive procedures by the occasional exstrophy surgeon is not recommended. **Selection should take into account phallic size and length, depth of the urethral groove, and size of the bladder template in those with delayed primary closures, as well as perivesical and urethral scarring in those who have undergone a prior failed closure** (Baird et al., 2005c; Gearhart et al., 1998; Gearhart and Jeffs, 1991a).

Management After Primary Closure

The initial step of the MSRE converts a patient with exstrophy into one with mid-penile shaft epispadias and incontinence. After the surgery, patients typically spend 3 days in the intensive care unit for optimizing pain control and weaning from ventilation. Adequate pain control may be achieved with a combination of tunneled epidural lidocaine administration and intravenous patient controlled analgesia (Stec et al., 2012b). **Before removal of the suprapubic tube, 4 weeks after surgery the bladder outlet is calibrated by a urethral catheter or a urethral sound to ensure free drainage. A complete ultrasound examination is performed to ascertain the status of the renal pelvises and ureters, and appropriate urinary antibiotics are administered because all patients have reflux after closure.** Residual urine is estimated by clamping the suprapubic tube, and specimens for culture are obtained before the patient leaves the hospital and at subsequent intervals to detect infection and ensure that the bladder is empty. If the initial ultrasound examination shows good drainage, upper tract imaging by ultrasonography is repeated 3 months after discharge from the hospital and at intervals of 6 months to 1 year during the next 2 to 3 years to detect any upper tract changes caused by reflux, infection, or obstruction. Prophylactic antibiotics should be continuous because all patients with bladder exstrophy, once it has been closed, have vesicoureteral reflux. If a useful continence interval has resulted from the initial closure, a further operation for incontinence may not be required; however, this situation is unusual. After the conversion from exstrophy to complete epispadias with incontinence, the bladder gradually increases in capacity as inflammatory changes in the mucosa resolve.

Cystoscopy and cystography at yearly intervals are used to evaluate the degree of reflux noted in almost 100% of patients and to provide an estimate of interval bladder growth (Gearhart and Jeffs, 1998). Even in a completely incontinent patient, bladder capacity gradually increases to a point at which the bladder can be distended at cystography to its true capacity. This must be done under anesthesia in young children because the values obtained differ markedly from those obtained when trying to fill the bladder of a crying, squirming infant on an x-ray table (Gearhart and Jeffs, 1998). If the bladder has not achieved a capacity of at least 30 mL by 1 to 2 years, concern must be voiced to the parents about the overall ability of the bladder to undergo a continence procedure. Currently, the best parameters available to predict overall success are the size of the bladder template at birth and a successful primary closure with absence of infections.

Should bladder outlet resistance be such that urine is retained within the bladder and reflux and ureteral dilation develop with infected urine, it may be necessary to dilate the urethra or to begin intermittent catheterization (Baker et al., 1999). Sometimes the posterior urethral obstruction can be such that it requires a transurethral incision of the stricture to maintain an adequate posterior urethral outlet. If bladder outlet resistance persists and infections continue, an antireflux procedure may be required as early as 6 months to 1 year after initial closure (Mathews and Gearhart, 2003). After primary CPRE repair, 50% of patients require ureteral reimplantation in the first year after closure. Because of this problem, some units are trying ureteral reimplantation at the time of bladder closure, but the numbers of patients treated in this fashion is small (Braga et al., 2010). If severe upper tract changes occur, surgical revision of the bladder outlet by advancing skin flaps into the orifice or even patching the stricture may be necessary to prevent scarring and further obstruction. As mentioned previously, transurethral incision of the urethral stricture to obtain a balanced outlet should be tried before surgical revision.

Judgment is required to know when to avoid attempts at functional closure and to know when to turn to urinary diversion as a means to preserve renal function. This change of plan is seldom necessary if an adequate outlet has been constructed at the initial closure and if careful attention has been paid to the details of follow-up of the bladder and posterior urethra. An important caveat is that if there are recurrent urinary tract infections (UTIs) and the bladder is distended on ultrasonography, cystoscopy should be performed. The posterior urethra should be carefully examined anteriorly for erosion of the intrapubic stitch, which may be the cause of the recurrent infections (Baker et al., 1999). If the intrapubic stitch is seen in the posterior urethra, a small suprapubic incision should be made and the stitch should be removed, or, if it can be grasped, it should be removed transurethrally. Husmann et al. (1990) have shown acceptable levels of upper tract function after primary closure if prophylactic antibiotics were used after initial closure and elevated urinary residuals were kept below 50 mL. In a recent study by Schaeffer et al. (2013), glomerular filtration rate (GFR) was measured before closure and 1 year after bladder neck reconstruction and was found to be no worse or higher than normal values.

Key Points: Management After Primary Closure

- Adequate bladder drainage
- Adequate ureteral drainage
- Adequate immobilization and movement control
- Adequate pain control

Selected Technical Aspects of Other Methods of Closure

Kelly Repair

The multiple-stage Kelly repair begins when the bladder is closed up to the level of the posterior urethra with no attempt to bring the pubic bones into apposition.

The second step of the Kelly repair, which differs from other types of repair, is the radical soft-tissue mobilization. This is accomplished by making an incision around the old bladder closure and by making parallel incisions on the urethral plate extending proximally to halfway between the ureteric orifices and the verumontanum. This maneuver helps expose the corpora laterally as they move over toward their insertion onto the pubis. The mucosa lateral to the urethra is excised, as is some of the mucosa of the bladder (Fig. 31.22A and B). The initial lateral extension of the incision exposes the dorsal nerves of the penis and the attachment of the corpora to the pubis (see Fig. 31.22B). The urethral plate is mobilized from the corporeal bodies and moved to below them to create a penoscrotal hypospadias.

FIG. 31.22 Kelly repair. (A) The penis has been degloved and pulled down over the scrotum. The corpora are exposed with their attachments to the pubis. The dorsal nerves of the penis are identified emerging from the pelvis superior to the attachment of the corpus to the pubis. (B) The extraperitoneal plane behind the left rectus muscle has been opened. The vas is identified and retracted with peritoneum. The external iliac vessels and obturator vessels and nerves are identified. The initial incision is made into the pubis to create a flake of bone, taking care to go down only to the level of the emergence of the dorsal nerve of the penis. (C) The pelvic floor is opened, and the bladder and rectum retracted medially. An incision is made through the levator medial to the white line. This incision is taken out to the wall of the pelvis so that the attachment of the levator to the back of the pubis will be moved with the bone flake. (D) Deeper, the ischiorectal fossa is encountered where the pudendal vessels are identified and freed up. Once the vessels and bone flake are totally free, the tissues of the penis, bladder neck, and urethra are reconstructed. (A and B, Redrawn from Kelly with permission.)

Laterally, the extraperitoneal space behind the rectus is entered and the vas is retracted (Fig. 31.22C). An incision is made in the superior aspect of the pubis downward, creating a “flake” to which the corpora of the penis and remnants of the urogenital diaphragm are attached medially (Fig. 31.22D). The incision is then taken deeper to the superior aspect of the levator ani. The incision is carried through the levator muscles both deeply and anteriorly to where the levators insert on the back of the pubis. The pudendal vessels and nerves are freed from any attachments. When it appears the entire course has been determined, the flake of the pubis is incised totally and the urethral and bladder neck area and muscles are brought together without tension.

Mitchell Repair

The Mitchell repair is often done after a few months of age. The former difference was that the urethra is separated from its attachments to the underlying corporeal bodies and pelvic diaphragm during the first stage of the procedure. Mitchell purports that this allows better posterior positioning of the bladder neck and posterior urethra into the pelvis. This combined bladder closure with penile repair was originally thought to be sufficient for the patient to achieve urinary continence, but this has been found not to be the case in that most of these patients require bladder neck repair (Gargollo et al., 2011; Gearhart et al., 2005; Shoukry et al., 2009).

The closure is begun in the standard fashion, but the incision is carried out onto the urethral plate, taking care to preserve its blood supply and avoiding corporeal injury. The penis is then somewhat disassembled into three components—the right corpus, left corpus, and urethral wedge (Fig. 31.23)—because it is believed that each corpora has its own blood supply. However, the urethral plate draws blood from spongiosa so that there can be ischemia. Recently, because of soft tissue loss, the repair has changed to become more like the Cantwell-Ransley repair by leaving the urethral plate attached to the glans (Borer et al., 2017). The dissection moves cranially and the intersymphyseal band is incised. This is also accomplished as in the MSRE procedure by going medial to the inferior aspect of the pubis and cutting these fibers from their posterior urethral attachment all the way down to the levator hiatus (Gearhart et al., 2007). During standard closure of the bladder, the bladder neck is tailored and the urethra is closed in an attempt to move the urethra to the tip of the penis (see Fig. 31.23). If it does not reach the tip of the penis, the urethra is taken to the base of the penis in a hypospadiac position in a majority (70%) of patients (see Fig. 31.23).

FIG. 31.23 Modified penile disassembly during complete primary repair of bladder exstrophy. (A) Dissection of the urethral plate in the ventral approach with the urethral plate attached distally to the corpora and glans. (B) Dorsal view shows dissection of the corpora from urethra until the distal centimeter for maintenance of vascular structure and symmetry, similar to the modified Cantwell-Ransley epispadias repair. (C) The bladder is closed and the urethra is tubulerized. (Modified from Gearhart JP, Mathews R: Penile reconstruction combined with bladder closure in the management of classic bladder exstrophy: illustration of technique. *Urology.* 55:764–770, 2000, *top.*)

The repair is very similar in the female patient, with care taken to mobilize the bladder neck, urethra, and vagina as a single unit. Unlike the Kelly repair but similar to MSRE, an osteotomy is used in both sexes if the child is older than 3 days old or the diastasis is judged to be excessive.

Penile and Urethral Closure in Exstrophy

Epispadias Repair

Historically, bladder neck reconstruction was performed before penile and urethral reconstruction. An increase in bladder capacity in patients with extremely small bladder capacities after epispadias repair prompted a change in the management program (Gearhart and Jeffs, 1989a) (see Fig. 31.19). In a group of patients with a small bladder capacity after initial closure, there was a mean increase of 55 mL in males only 22 months after epispadias repair. However, with MSRE, the epispadias repair is now performed at about 6 to 10 months of age in all patients. Recent data by Kufner et al. (2010) clearly demonstrated better eventual overall bladder capacity in patients in whom the epispadias repair was completed before 12 months of life. With this modification, possibly all patients can achieve an appropriate capacity by the time they are physically and mentally ready to undergo bladder neck reconstruction. Because most boys with exstrophy have a somewhat small penis and a shortage of available penile skin, all patients undergo testosterone stimulation before urethroplasty and penile reconstruction (Gearhart and Jeffs, 1987).

Many techniques have been described for reconstruction of the penis and urethra in patients with CBE. Current methods of epispadias repair in bladder exstrophy are the Cantwell-Ransley repair (1989), the modified Cantwell-Ransley repair (1995), and the penile disassembly technique described by Mitchell and Bägli (1996).

Regardless of the surgical technique chosen for reconstruction of the penis in bladder exstrophy, four key concerns must be addressed to ensure a functional and cosmetically pleasing penis. These concerns are (1) correction of dorsal chordee, (2) urethral reconstruction, (3) glanular reconstruction, and (4) penile skin closure.

Although it is possible to achieve some penile lengthening and release of chordee at the time of initial closure, it is always necessary to perform formal penile elongation with release of chordee at the time of urethroplasty in exstrophy patients. Data of Silver et al. (1997b) clearly showed that this is more of an apparent lengthening of the penis than a true lengthening because the anterior corporeal bodies in exstrophy patients have 50% less length than age-matched controls. All remnants of the suspensory ligaments and old scar tissue from the initial bladder closure must be excised. Further dissection of the corpora cavernosa from the inferior pubic ramus can be achieved. It is often surprising how little is accomplished in freeing the corporeal bodies from the pubis at the time of initial exstrophy closure (Gearhart, 1991).

Lengthening of the urethral groove is also essential. In the penile disassembly technique described by Mitchell and Bägli (1996), the urethral plate is dissected completely from the glans; in more than 70% of patients it is not long enough to reach the tip of the penis, and as a result hypospadias is present, with further reconstruction needed at another time (Hafez and El-Sherbiny, 2005).

Chordee

Besides lengthening of the urethral groove, dorsal chordee must be addressed. To release dorsal chordee, surgeons may lengthen the dorsomedial aspect of the corpora by incision and anastomosis of the corpora (Gearhart et al., 1992). Also, length can be gained by placement of a dermal graft to allow lengthening of the dorsal aspect of the corpora (Woodhouse, 1986). However, most of these techniques, especially grafting, are reserved for patients who are seen in adolescent and adult years for epispadias surgery with the need for some increased penile length and correction of residual chordee.

Urethral Reconstruction

Urethral reconstruction is an important aspect of external genital reconstruction in exstrophy. This can be accomplished by many previously reported methods, most of which have been abandoned: (1) tubularization of dorsal urethral groove; (2) free grafts of genital and extragenital skin; (3) ventral transverse island flaps; and (4) double-faced ventral island flaps. Most modern techniques of epispadias repair associated with bladder exstrophy use tubularization of the urethral plate, moving the urethral plate under the corporeal bodies after closure to lessen the incidence of urethrocutaneous fistula, to give the penis a more downward deflection, and to make a more easily catheterizable urethral channel (Surer et al., 2000). With the penile disassembly technique, interrupted sutures are often used to try and get the urethra to the tip of the penis again after it is completely detached, with resultant hypospadias in many. Although some authors have described the ease and success of hypospadias repair after penile disassembly (Shnorhavorian et al., 2008), a large European study (Berrettini et al., 2011) found the opposite with a 50% complication rate. Patients who did well underwent a two-stage repair and placement of a graft before urethroplasty.

Our preference for urethroplasty and penile reconstruction, if the urethral groove has adequate length, is the modified Cantwell-Ransley repair (Gearhart et al., 1992, 1995c, 2005) (Fig. 31.24). Currently, in the modern applications of the staged reconstruction of bladder exstrophy, epispadias repair is performed when the child is 6 to 10 months of age. At the time of primary closure the urethra is closed well up on the penile shaft.

(E) Dissection of the foreskin on the ventral aspect of the penis. (F) The corpora are dissected off the urethral plate, and parallel incisions are made into the glans to create glans wings. Note the lateral position of the neurovascular bundles (NVB) *(inset).* (G) The urethra is tabularized using a continuous running suture. (H) Approximation of the corpora using the incisions in the corpora if indicated. (I) Corpora approximated above the urethra to provide an anatomically ventral location of the urethra *(see inset).* (J) Glans is reconstructed in two layers. (K) Preparation for skin closure. (L) Suture is placed at the base of the penis to locate the foreskin on the shaft of the penis as well as to provide an area of distinction between the penis and the scrotum. (M) Foreskin is sewn to the coronal sulcus. (N) Completion of the repair with resurfacing of the penis and use of a proximal Z-plasty incision to provide downward penile deflection. (Copyright Brady Urological Institute.)

The modified Cantwell-Ransley procedure is begun by placing a transverse stitch through the glans as a traction stitch. Incisions are made over two parallel lines marked previously on the dorsum of the penis that outline an 18-mm–wide strip of urethral mucosa, extending from the prostatic urethral meatus to the tip of the penis (see Fig. 31.24A). For this procedure, a deep vertical incision is made in the urethral plate distally. The incision is then closed with 6-0 polyglycolic sutures in a transverse fashion (see Figs. 31.24B to D). This procedure flattens the distal urethral plate and advances the urethra to the tip of the phallus so that it will be in excellent glanular position when the glanular wings are closed over the reconstructed urethra. Glanular mucosal areas of the dorsal glans are excised adjacent to the urethral strip, and thick glanular flaps are constructed bilaterally (see Fig. 31.24F). Lateral skin flaps are mobilized and undermined. A Z incision of the suprapubic area permits wide exposure and division of the suspensory ligaments and old scar tissue from initial exstrophy closure (see Fig. 31.24F).

Ventral penile skin is taken down to the level of the scrotum (see Fig. 31.24E). Care is taken to preserve the mesentery to the urethral plate, which arises proximally and extends upward between the corporeal blood supply to the urethral plate. Dissection of the corpora is begun ventrally with dissection on the surface of Buck fascia covering the corporeal bodies. The plane is followed closely until one exits on the dorsum of the penis between the corpus spongiosum and the corporeal body, first on one side and then on the other (see Figs. 31.24F and G). Vessel loops are placed around the corporeal bodies, and the dissection is extended proximally on the corpora to dissect the urethral plate free from the corporeal bodies up to the level of the prostate. Although difficulties may be expected when dissecting proximally where the paraexstrophy skin flaps had been sutured to the urethral plate, this has not been encountered in our experience, and dissection is kept just on the corporeal bodies while proceeding proximally. The urethral plate is also dissected distally past the level of the junction of the glans with the corporeal bodies. In this manner, adequate mobilization is obtained, and it is not difficult to bring the corporeal bodies over the urethra at the level of the corona. This separates the penis into three components: the two corpora and the urethral plate (see Fig. 31.24F). Complete penile disassembly is not undertaken, because the most distal 1-cm attachment of the mucosa plate to the glans is left intact (Surer et al., 2000).

The neurovascular bundles, situated between Buck fascia and the corporeal wall, are typically left intact in young patients if rotation of the corporeal bodies over the urethra effectively straightens the penis. If not, the neurovascular bundles are dissected free from the corporeal bodies, with vessel loops being placed around these structures so that the neurovascular bundles will not be compromised when incisions are made in the corpora and the corpora are rotated medially over the neourethra (see Fig. 31.24H). After the corporeal bodies are incised or rotated over the urethra, the urethral strip is closed in a linear manner from the prostatic opening to the glans over an 8-Fr silicone stent with 6-0 polyglycolic acid sutures. After this is accomplished, incisions are made in the corporeal bodies at the point of maximum curvature, opening a diamond-shaped effect in the erectile tissue (see Fig. 31.24H). The corpora are then closed over the neourethra with two running sutures of 5-0 PDS, and the diamond-shaped defects in the adjacent area of the corpora are sutured to each other. This procedure effectively displaces the urethra ventrally in a normal position. This not only causes the downward deflection of the penis but also allows some additional length by dorsal rotation and approximation of the corporeal bodies over the neourethra. After the urethra has been transferred to the ventrum, further sutures of 4-0 polyglycolic acid are placed between the corporeal bodies to bury the urethra further, especially at the level of the junction of the glans and the corporeal bodies at the corona (see Fig. 31.24I).

The glans wings are then closed over the glanular urethra using subcuticular sutures of 5-0 polyglycolic acid, and the glans epithelium is closed with 6-0 polyglycolic acid sutures (see Fig. 31.24I). The ventral skin is then brought up and sutured to the ventral edge of the corona, and the flaps are fashioned to provide adequate coverage and lengthening of the dorsum of the penis. The skin is reapproximated with interrupted 5-0 or 6-0 polyglycolic acid sutures (see Figs. 31.24K to M). A Z-plasty at the base of the penis is closed with interrupted 5-0 or 6-0 polyglycolic acid sutures. A silicone stent is left indwelling in the neourethra to provide drainage for 10 to 12 days (see Fig. 31.24).

Penile Skin Closure

If skin closure continues to be a problem in genital reconstruction because of the paucity of skin associated with this condition, a Z-plasty incision and closure at the base of the penis prevents skin contraction and upward tethering of the penis. The ventral foreskin can be split in the midline and brought to the dorsum as lateral preputial flaps for coverage of the penile shaft. If the flaps are a bit asymmetrical, a staggered dorsal suture line results, with less upward tethering. Alternatively, a buttonhole can be created in the ventral foreskin and simply transposed to the dorsum for additional penile skin coverage. All patients in our series are given testosterone enanthate 2 mg/kg intramuscularly 5 weeks and 2 weeks before repair.

Postoperative Problems

Postoperative pain and bladder spasms after extensive external genital reconstructive surgery require a combined effort of the pediatric anesthesia pain service and the surgical service. Controlling bladder spasms is paramount because they are associated with urinary extravasation and fistula formation. All of our patients have a caudal epidural catheter placed at the time of surgery, and oxybutynin is started immediately after surgery to decrease the incidence of bladder spasms and enhance the patient's comfort. At the time of discharge, the plastic dressing on the penis is left intact and the child is discharged with narcotics, antispasmodics, and appropriate broad-spectrum antibiotic coverage.

Female Exstrophy

The principles of repair of female and male exstrophy are similar. However, in the female patient we recommend the following: (1) radical dissection of the bladder and urethra from surrounding structures while connection to the vagina is maintained; (2) dissection of the lateral aspects of the posterior vesicourethral and vaginal unit from their attachments to the urogenital diaphragm; (3) tension-free closure of the abdomen, bladder-urethra, and external genitalia; and (4) judicious use of osteotomy and proper immobilization of the pelvis and extremities.

As in the male patient, if the pelvic bones are separated over 4 cm or are not malleable under anesthesia, an osteotomy is then performed. The transverse innominate osteotomy along with vertical iliac osteotomy is commonly used in our practice. Interfragmentary pins are placed and the fixator is applied after the soft-tissue surgery has been completed. An interesting finding in more than 1287 exstrophies in our institutional-approved database is that even with a large bladder template the diastasis tends to be narrower in female than in male patients. Thus closure in female exstrophy patients is easier to perform, and female patients do not require an osteotomy as commonly as male patients.

The vagina is prepared with an iodine preparation so that if it is violated during the dissection it can simply be closed. In the closure, we start our dissection along the medial aspect of the clitoral or corporeal halves and move deeply into the pelvis. Pinpoint electrocautery at a low setting is used to limit bleeding and tissue injury. The dissection of the vagina proceeds laterally and posteriorly. The urethrovaginal septum is left intact to preserve its blood supply. As in the male patient, the dissection proceeds posterior and downward until the levator hiatus is reached, with the urogenital diaphragm fibers lateral and posterior to the vesicourethral plate and vaginal incision. This maneuver allows placement of the unit deeply into the pelvis and, more important, keeps it from being displaced anteriorly when the pelvic bones are brought together.

The bladder is closed with a single figure-of-eight layer of 3-0 polyglactin suture to maximize postclosure bladder volume. The urethra is closed with a single layer of 4-0 to 5-0 polyglactin depending on the thickness of the tissue. An indwelling suprapubic tube is brought out through the dome of the bladder along with two small feeding tubes that act as stents and are left in place for 4 full weeks. These exit the neoumbilicus as described by Hanna (1986). No tubes are brought out through the neourethra because this can be associated with wound infection and prolapse or dehiscence. A No. 2 nylon suture in a horizontal mattress fashion is used to bring the pubic bones into apposition. Once the pubic bones are brought together, a routine subcutaneous and skin closure are performed. A mons plasty is then performed, and the subcutaneous tissue of the clitorides are brought together with 5-0 polyglactin and the epithelium with 6-0 polyglactin sutures. If needed, a Y-V labioplasty is performed for better exteriorization of the vaginal introitus.

If an osteotomy has been performed, the external fixator is then placed and a pelvic x-ray study is obtained. If pin and fixator placement are optimal, then the infant is placed in modified Buck traction for 4 weeks. If an osteotomy was not performed, the infant is placed in Bryant traction for 4 weeks. Postoperative care is the same as in the male patient, with an indwelling epidural catheter and bladder spasms controlled by the epidural and oral oxybutynin.

Continence and Antireflux Procedure

Although some modern exstrophy repair methods are claimed to establish suitable continence without formal bladder neck repair, many patients are referred to our unit still incontinent after only prior newborn repair or after newborn repair and multiple injections of various substances into the bladder neck area. Likewise, other groups have reported their outcomes with newborn repair, and most have recommended some sort of outlet procedure. In our unit each child has a cystoscopy and gravity cystogram under anesthesia yearly after newborn closure to assess bladder growth. Prior data by Gearhart and Jeffs have shown that after newborn exstrophy closure there should be an average increase in bladder capacity of 54 mL in 24 months (Gearhart and Jeffs, 1989b). Chan et al. (2001) found that in selected exstrophy patients who underwent closure, epispadias repair, and bladder neck reconstruction at our institution, a median bladder capacity of 100 mL was more common in the group of patients who were completely dry after bladder neck reconstruction. Most of these children were 5 to 7 years of age and were ready emotionally, maturationally, and intellectually to participate in a postoperative voiding program. An intense pre–bladder neck repair program is conducted by a senior urology nurse practitioner, senior clinical nurses, and a child psychologist well versed in voiding issues. These sessions are begun for the child and parents at least 6 months before an outlet procedure. Successful completion of the program is required before surgery is scheduled.

Continence and antireflux procedures performed at our institution are illustrated in Fig. 31.25. Most patients with reflux are safely managed conservatively with prophylactic antibiotics until their bladder neck reconstruction is performed. However, a small population of patients may require ureteral reimplantation before a bladder neck procedure in the event of pyelonephritis, recurrent UTIs, worsening hydronephrosis, or decreasing renal function (Tourchi et al., 2015). The bladder is opened through a transverse incision at the bladder neck with a vertical extension. The later midline closure of this incision is the width of the bladder neck and enlarges the vertical dimension of the bladder, which in exstrophy is often short (see Fig. 31.25A). A Cohen transtrigonal ureteral reimplantation or a cephalotrigonal reimplantation is performed to move the ureter across the bladder, above the trigone, or to direct the ureter cephalad up onto the edge of the trigone (see Fig. 31.25B and C; Canning et al., 1992). If the ureters are low on the trigone and there is a need to move the ureteral hiatus higher, the hiatus is simply cut in a cephalad direction, and cross-trigonal reimplants are performed at the upper aspect of the trigone (see Fig. 31.23C).

FIG. 31.25 Modified Young-Dees-Leadbetter bladder neck reconstruction. (A) Vertical bladder incision with distal transverse extension where the bladder and posterior urethra are under the pubic bar. (B and C) Ureters are identified, mobilized, and reimplanted in a cephalotrigonal position. (D and E) Segments of mucosa are excised from either side of a median strip (1.5 cm × 3 cm) that will form the neourethra. Short incisions in the muscle will permit extension of the bladder neck. (F) Urethra is tabularized using a continuous running suture. (G) Posterior urethra and bladder neck are reconstructed. (H and I) Bladder muscle is brought together in a double-breasted fashion over the neourethra. (J) Bladder closure is completed and the distal suspensory sutures are tied over the abdominal wall *(see inset).* Suprapubic tube and stents are left in place; however, the urethra is left unstented. (Copyright Brady Urological Institute.)

The continence procedure is begun by selecting a posterior strip of mucosa 15 mm wide and 30 mm long that extends distally from the mid-trigone to the prostate or posterior urethra (see Fig. 31.25D). Bladder muscle lateral to the mucosal strip is denuded from the mucosa. It is often helpful at this juncture to use one or two epinephrine-soaked sponges to aid in the control of bleeding and the visualization of the denuded area. Tailoring of the denuded lateral muscle triangles is aided by multiple small incisions on the free edge bilaterally that allow the area of the reconstruction to assume a more cephalad position (see Fig. 31.25E). **These muscle flaps not only are smaller but also are not incised transversely at their cephalad extent as described in the original Young-Dees procedure to prevent denervation and ischemia. The basic premise is to create a mucosa-lined tube inside a muscular funnel that narrows from its junction with the floor of the bladder that extends caudally.** The edges of the mucosa and underlying muscle are closed with interrupted sutures of 4-0 polyglycolic acid (see Fig. 31.25F). The adjacent denuded muscle flaps are overlapped and sutured firmly in place with a 3-0 PDS to provide reinforcement of the bladder neck and urethral reconstruction (see Figs. 31.25G to I). An 8-Fr urethral stent may be used as a guide during posterior urethral and bladder neck reconstruction but is removed after the repair is completed. After the bladder neck repair is completed, the repair is suspended to the rectus fascia (see Fig. 31.25J, *inset*).

Very radical dissection of the bladder, bladder neck, and posterior urethra is required, not only within the pelvis but also from the posterior aspect of the pubic bar to provide enough mobility for the bladder neck reconstruction. This maneuver allows adequate bladder neck narrowing and tightening of the bladder neck repair and subsequent anterior suspension of the newly created posterior urethra and bladder neck. In patients after CPRE repair in the newborn period who had a vesicocutaneous fistula after closure, great care must be taken anteriorly during mobilization of the bladder neck because the tissues are more adherent to the back of the intrasymphyseal bar. If visualization of the posterior urethra is problematic, the intrasymphyseal bar can be cut, thus providing a widened field of exposure. The intrasymphyseal bar is approximated with 2-0 sutures of PDS. If the intrasymphyseal bar is cut, abduction of the lower extremities should be restricted in the postoperative period to allow proper healing of the intrasymphyseal bar.

Postoperative Care

Ureteral stents are placed in the reimplanted ureters and brought out through the wall of the bladder, and the bladder is drained by suprapubic tube, which is left indwelling for a 3-week period. **At the end of 4 weeks the suprapubic tube is clamped and the patient is allowed to attempt to void. Initially, the tube should not be clamped for more than 1 hour. If voiding does not occur, the child is given an anesthetic and an 8-Fr Foley catheter is placed**. This is left in place for 5 days, then removed, and another voiding trial is begun. This part of the postoperative period is most demanding on the patient and family. Some children require several catheter placements before voiding is initiated. If the child can empty the bladder satisfactorily, the suprapubic tube is removed. Frequent bladder and renal ultrasound examinations are required in the first few months after bladder neck repair.

Modern Initial Repair of Bladder Exstrophy: Outcomes and Results

The use of functional reconstruction in bladder exstrophy has resulted in dramatic improvement in the success of reconstruction. Several series (Purves and Gearhart, 2008; Shnorhavorian et al., 2008) have demonstrated the success and applicability of early newborn closure with or without pelvic osteotomy. Important older series have shown acceptable continence rates with preservation of renal function in a majority of patients treated in early life.

Two of the most reliable predictors of eventual urinary continence are the size of the bladder template at birth and a successful primary closure. Regardless of the technique used, a complication-free newborn closure of the abdomen, pelvis, bladder, and proximal or complete urethra paves the way for an optimal long-term result. A very large series by Surer et al. (2001) demonstrated the importance of a successful primary closure in a large group of exstrophy patients who underwent early closure. At other centers 68 patients (57 male and 11 female patients) were referred for bladder neck reconstruction after primary closure; 20% had concomitant pelvic osteotomy at the time of closure. The majority of patients underwent closure within the first 72 hours of life. Mean capacity at the time of bladder neck repair was 121 mL. The results were that 83% were continent and voiding per the urethra. This application of early successful closure and follow-up reconstruction by a second surgeon shows convincingly that a successful primary closure is one of the most important determinants of eventual bladder capacity and continence regardless of who originally performed the repair.

Initial Closure

Long-term data on all modern types of exstrophy repair can be difficult to obtain. Nonetheless, this section addresses what has been gleaned from the recent literature. Most data come from the MSRE and CPRE groups. In a large series reported by Hernandez et al. (2008), clinical information from 189 patients who had undergone primary closure between 1988 and 2004 was extracted from our exstrophy database. The records of 131 patients (95 males) who underwent MSRE with a modified Cantwell-Ransley repair by a single surgeon in 1988 to 2004 were reviewed with a minimum 5-year follow-up. The importance of a successful initial closure is emphasized by Oesterling and Jeffs (1987) and Husmann et al. (1989a), who found that the onset of continence was quicker and the continence rate was higher in those who underwent a successful primary closure with or without osteotomy. In addition, Novak et al. (2010) reported on patients with bladder exstrophy who underwent more than one attempt at primary closure. If a patient underwent two closures, the chance of having an adequate bladder capacity for bladder neck repair was 60%, and the chance of voided continence was 17% overall. Patients who underwent three closures had only a 50% chance of an adequate capacity and less than a 16% chance of voided continence. In an evaluation of this select group, it was found that at the time of primary closure, 80% of patients had no form of pelvic osteotomy. Thus the chance of achieving an adequate bladder capacity and eventual continence after more than one exstrophy closure is markedly diminished. These very poor results underline the importance of a secure abdominal, bony pelvis and posterior vesicourethral unit in the newborn with exstrophy.

Also, compared with many of the other repairs, data are available from several units on their results with the CPRE repair. In a series by Shnorhavorian et al. (2008), 2 of 39 patients had dehiscence of the fascia and 9 of 39 developed a vesicocutaneous fistula. Complications seen in the CPRE repair are as much as those seen in MSRE. However, some are particular to this repair. A large series of vesicocutaneous fistulae was reported from a single institutional study; some patients had an osteotomy, and others did not (Shoukry et al., 2009). In addition, several series have reported the need for early ureteral reimplantation after closure and the occurrence of significant upper tract changes in many patients (Grady and Mitchell, 1999). This has prompted the call for ureteral reimplantation at the time of exstrophy closure by one group (Braga et al., 2008).

Although many earlier published series were small, the incidence of bladder prolapse and dehiscence is reported to be low. However, in a recent large series of primary CPRE repairs by Shoukry et al. (2009), the incidence of major prolapse and dehiscence was 15.8% even with the use of osteotomy. In this author's series we have seen a number of referred patients with complete dehiscence and major bladder prolapse after newborn CPRE repair. However, the other complicating factors we have seen, in addition to the aforementioned, have been significant losses of soft tissue including partial or complete loss of the penile glans in 9 patients and the loss of the urethrovaginal septum in 2. In a series by Hammouda (2003), 5 of 42 patients had ischemic loss of glans tissue after CPRE repair. Thus the complications of primary closure between CPRE and MSRE are similar, but much more serious if soft-tissue loss occurs.

In a report using the Erlangen repair by Rosch et al. of 100 closures, the complications in general were mild, with urethrocutaneous fistulae in 2%, minimal hydronephrosis in 20%, and severe hydronephrosis requiring further surgery in 3% (Rosch et al., 2001). There were no incidents of bladder prolapse or dehiscence. Osteotomy was not used in any patient, but a very sophisticated coaptation technique involving the obturator foramen was used in all patients.

Interest in the outcomes of exstrophy closure has expanded to interest in the economic outcomes of the treatment of this major birth defect and who should be doing these types of operations in the newborn. In a paper by Nelson et al. (2005b), high-volume hospitals (those closing more than five exstrophies per year) had lower overall costs per patient than low-volume hospitals (fewer than five exstrophies per year). In addition, Nelson et al. (2008) found that a successful newborn closure had overall markedly lower inflation-adjusted hospital charges than reclosures as a result of shorter operating times and shorter length of stay.

A corollary to these papers was one from Meldrum et al. (2005), who found that when exstrophy closures failed and the exstrophy had to be reclosed, the success rates and ultimate continence were better in patients of fellowship-trained pediatric urologists than those of other surgeons (general urologists, non–fellowship-trained pediatric urologists, and general pediatric surgeons).

In the evaluation of this group of selected exstrophy patients, it was found that at the time of initial closure, 19 of 23 patients had no osteotomy; 6 of the patients had obtained bladder capacity suitable for bladder neck reconstruction; 3 were dry, and 3 were incontinent. Bladder size was inadequate in 9 patients who had been monitored for bladder growth. The chance of achieving an adequate bladder capacity and eventual continence after more than one closure attempt is markedly diminished. Last, the importance of early initial closure was emphasized by Husmann et al. (1989a), who showed that only 10% of the patients who undergo bladder closure before 1 year of age, but 40% of those who undergo the procedure at a later age require eventual augmentation.

Epispadias Repair

Although urinary incontinence remains the most significant problem for patients with CBE and epispadias, anxiety about inadequate and unattractive genitalia still poses the greatest concern to male patients. We began using the modified Cantwell-Ransley repair in patients with classic exstrophy or epispadias in 1988 and have reported our early experience (Gearhart et al., 1992, 1995c).

Since 1988 the modified Cantwell-Ransley repair has been performed for 129 male patients with either CBE (97 patients) or epispadias (32 patients) (Baird et al., 2005b). At the time of surgery, the patients' ages ranged from 1 to 18 years with an average age of 19 months. Of the 97 patients with bladder exstrophy, 31 had a short urethral groove requiring paraexstrophy skin flaps for penile lengthening at the time of initial bladder exstrophy closure. Of the 32 epispadiac patients, 26 had penopubic and 6 had penile epispadias at presentation.

This technique was used for primary urethroplasty in 106 patients with bladder exstrophy and 32 with epispadias. The modified Cantwell-Ransley repair was used as a secondary procedure after failed urethroplasty in 15 patients with exstrophy and 8 with epispadias and was combined with reclosure of bladder exstrophy in 18 patients. Early epispadias repair was performed when the patients were 6 months to 1 year of age. However, because of concerns about getting the urethra deeper under the corpora at the glanular level, beginning in 1994 we further modified the Cantwell-Ransley repair by detaching the mucosal plate from the corona except for the distal 0.5 to 1 cm of the plate inside the glans.

While standing, 120 patients had a horizontal or downward-angled penis. The incidence of urethrocutaneous fistula in the immediate postoperative period was 16%, and at 3 months it was 12%. Nine patients developed a urethral stricture of the proximal anastomotic site, and 12 had minor skin separation of the dorsal skin closure. Cystoscopy with catheterization in 120 patients revealed an easily negotiable channel in all; 8 patients required further penile straightening surgery; 15 patients older than 16 years had engaged in satisfactory intercourse. All reported orgasms and ejaculation with a straight penis on erection. One patient reported that his penis was shorter after surgery.

Modern penile reconstructive techniques should create a straight and functional penis with a glanular meatus, an easily catheterizable neourethral channel (if needed), and an acceptable cosmetic appearance. Many adolescents considered their odd-appearing genitalia with a short, widened penis upwardly deviated to be a greater psychosocial problem than incontinence, and therefore every effort should be made to restore the penis to a normal condition. In 1989 Ransley et al. introduced a concept to release dorsal chordee by incision and anastomosis of the dorsomedial aspect of the corpora over the urethra and urethral meatotomy at the distal end of the glans, to move the meatus to a more normal position and secure good direction of the urinary stream (reverse MAGPI [meatal advancement and glansplasty incision]) (Ransley et al., 1989). Ransley's group has reported its long-term experience with 95 patients in whom the modified Cantwell-Ransley repair was used: fistula occurred in only 4% of patients, and a urethral stricture in only 5% (Kajbafzadeh et al., 1995).

Dissection of the urethral strip to inside the glans penis provides a ventral position of the urethra and the glans and submerges the urethra well below the corpora at the glans level. This approximation of raw surface of glanular tissues dorsally over the urethra is clearly why the incidence of fistula in the area of the corona is rare compared with the Young repair. Fistulae in our patients usually appear at the base of the penis, where the urethra comes up proximally between the corporeal bodies. In patients who have had a prior failed exstrophy closure, failed epispadias repair, or have recurrent urethrocutaneous fistulas leading to a limited reserve of tissue, a tunica vaginalis flap, harvested from one of testicles, may be used during the reconstruction of the urethra to minimize the rates of fistulization (Lue et al., 2015).

In modern exstrophy reconstructive techniques, most surgeons try to preserve the urethral plate at the time of exstrophy closure. Because the use of paraexstrophy skin flaps has been associated with the development of strictures, the use of these flaps is limited to selected patients in whom penile lengthening cannot be achieved with standard techniques.

Papers from several institutions have reported their results with the Mitchell-Bägli penile disassembly technique. Complications are similar to those of other methods of epispadias repair (i.e., fistula and urethral stricture) (Kibar et al., 2009a; Zaontz et al., 1998). Although not a complication, a high percentage are made hypospadiac as the completely dissected urethral plate fails to reach the tip of the glans. The rate of being made hypospadiac has been reported as 38% to 83% (El-Sherbiny and Hafez, 2005; Mitchell and Bägli, 1996).

As mentioned in the prior section on exstrophy closure, ischemic loss of the glans, urethral plate, and corpora have been reported by Hammouda (2003) and Husmann and Gearhart (2004) after penile disassembly. Cervellione et al. (2010) have reported the largest series of penile ischemic injury in the exstrophy-epispadias spectrum. Most occurred at the time of exstrophy closure, and 19 of 24 did not have a pelvic osteotomy. The suggested explanation by the authors was compression of the pudendal vessels as a result of tension after pelvic apposition and/or direct injury to the pudendal vessels. Stopping the closure and doing an immediate osteotomy while the vessels had time to regain flow was the recommended course of action.

Repair of the hypospadias in these patients has been reported by the Seattle group as not difficult or associated with major complications. However, data from Hafez and El-Sherbiny (2005) and Gearhart and Baird (2005) show that difficulties can be associated with these repairs. In an attempt to deal with the issues and prevent them, El-Sherbiny and Hafez (2005) and Perovic et al. (1999) have modified the Mitchell repair to resemble the modified Cantwell-Ransley repair (Gearhart and Baird, 2005) by keeping the urethral plate attached to the distal glans to obviate the need for making the child hypospadiac at the time of isolated epispadias repair or when associated with CPRE.

In our opinion, none of the current epispadias repairs offers any significant gain in penile length by removal of the entire urethral plate from the glans or even the use of a free graft. Data reported by Silver et al. (1997b) clearly showed that although anterior corporeal length is significantly less in patients with exstrophy, posterior corporeal length is normal. These findings suggest that penile lengthening procedures at the time of epispadias repair improve apparent penile length and straighten the penis but do not transfer additional tissue (i.e., length) to the corporeal bodies. We have observed that the modified Cantwell-Ransley repair effectively corrects corporeal chordee and adds some penile length, and it can be hoped that dorsal penile curvature, often seen at puberty, will be lessened. In our significant experience with adolescent exstrophy males with significant dorsal chordee, we agree with Perovic et al. (1999) that movement of the neurovascular bundles along with incision and grafting of the resultant defect gives better results long term than incision and corpora cavernostomy. Typically in our experience, incision and rotation are used only for older patients with marked chordee. In the patients in whom corporeal rotation is used without corporeal incision and anastomosis, the neurovascular bundle is left intact and not dissected from its bed. Although review of findings reveals that almost all penises are straight or deflected downward, many of these patients are still young children. The long-term assessment of penile and urethral reconstruction in exstrophy patients by the modified Cantwell-Ransley repair has shown that in patients with bladder exstrophy and epispadias there is some increase in penile length, and a relatively straight penis with an adequate urethral caliber, which is adequate to void and ejaculate through, can be achieved with minimal morbidity. Long-term reports with the penile disassembly technique have also demonstrated a reasonably straight penis (Grady, 2003).

Bladder Neck Repair

Bladder neck reconstruction results in the exstrophy population have been reported by several groups. Some extensive experiences have come from the European groups in Lyon and Paris. Mouriquand et al. (2003) reported on 80 children with bladder exstrophy and 25 with incontinent epispadias. Follow-up ranged from 1 to 11 years; 45% of the group with exstrophy and 52% of those with epispadias had a dry interval longer than 3 hours. Although the continence rate was low, many of the exstrophy patients did not undergo closure until 6 to 12 months of age. Many underwent epispadias repair after bladder neck reconstruction, a factor known to influence eventual capacity and continence. Lottmann et al. (1998) presented a long-term follow-up study of Cendron's exstrophy patients who underwent complete reconstruction. With the Young-Dees repair, Lottman et al. (1998) were able to achieve urinary continence in 71% of male patients and 53% of female patients. Overall continence was 65% with a mean follow-up of 12 years after bladder neck repair. Series from North America using mainly the classic Young-Dees-Leadbetter repair reported continence rates ranging from 60% to 82% (Chan et al., 2001; Cole et al., 2003; Franco et al., 1994; Husmann et al., 1989a; McMahon et al., 1996; Mergurian et al., 1991; Perlmutter et al., 1991; Table 31.2). **The most important long-term factor gleaned from a review of all these series is the fact that bladder capacity at the time of bladder neck reconstruction is the most important determinant of eventual success.**

TABLE 31.2

Urinary Continence After Functional Bladder Closure

	BAIRD AND GEARHART ET AL. (2007)	PURVES ET AL. (2008)	SCHAEFFER ET AL. (2011)
No. of closures evaluated	67[a]	41[b]	27[c]
Patients confirmed dry day >3 h; dry hours[d]	70%	74%	56%

[a] All male.

[b] All female.

[c] Young-Dees-Leadbetter procedure after complete primary repair of exstrophy as newborn.

[d] Patients reported that they were dry for more than 3 hours during the daytime.

Data from Baird AD, Nelson CP, Gearhart JP: Modern staged repair of bladder exstrophy: a contemporary series, *J Pediatr Urol* 3(4):311–315, 2007; Purves JT, Baird AD, Gearhart JP: The modern staged repair of bladder exstrophy in the female: a contemporary series, *J Pediatr Urol* 4:150, 2008; Schaeffer AJ, Stec AA, Purves JT, et al: Complete primary repair of bladder exstrophy: a single institution referral experience, *J Urol* 1886:1041, 2011.

Records of 95 patients who underwent all stages of MSRE by a single surgeon at our institution between 1988 and 2004 were reviewed by Baird et al. (2007); 67 patients with bladder neck reconstruction and minimum 5-year follow-up were available for analysis. The current voiding status of each patient was obtained from parental or patient interview or direct observation by the nursing and physician staff. The patients were categorized as spontaneous voiding not on intermittent catheterization and were assigned a status of (1) completely dry—day and night; (2) socially continent—dry at least 3 hours during the day with occasional wet nights; or (3) wet—dry for less than 3 hours during the day and wet at night (Table 31.3).

TABLE 31.3

Urinary Continence After 67 Initial Bladder Neck Reconstructions

RESULT	AVERAGE DRY INTERVAL	NO. OF PATIENTS	% OF PATIENTS
Continent	3 hours	47	70%
Social continence (dry daytime, occasional wet nights)	3 hours	7	10%
Wet	<3 hours	13	19%

Of the 67 male patients who underwent bladder neck repair, the mean age for primary closure was 4 months (range, 6 hours to 4 months). The mean age at bladder neck repair was 4.8 years (range, 40 to 60 months), and these patients had a mean bladder capacity before repair of 98 mL (range, 75 to 185 mL). Of the 67 patients, 47 (70%) are continent and voiding urethrally without the need for augmentation or intermittent catheterization. Seven patients (10%) had social continence with occasional wet nights. The renal units of all patients who underwent bladder neck repair were evaluated by intravenous pyelography or ultrasound postoperatively on multiple occasions to assess preservation of renal function after the outlet procedure. One patient had reflux and hydronephrosis after the outlet procedure and bilateral reimplantation and developed left pyelonephritis with resultant mild scarring. Dimercaptosuccinic acid (DMSA) scanning revealed nearly normal bilateral renal function. Conservative follow-up revealed resolution of the reflux with time. One patient developed ureteral obstruction and required reoperative reimplantation. Prolonged outlet obstruction required cystoscopy and placement of an 8-Fr catheter in 19 patients, and prolonged suprapubic drainage was required in 13 patients. Thirteen (19%) failed bladder neck repair completely; 6 have undergone continent diversion, and 7 await further surgery. The mean time to daytime continence was 14 months (range 4 to 23 months), and the mean time to nighttime dryness was 23 months (range 11 to 34 months). No correlation was found between age at bladder neck reconstruction and age at achievement of continence.

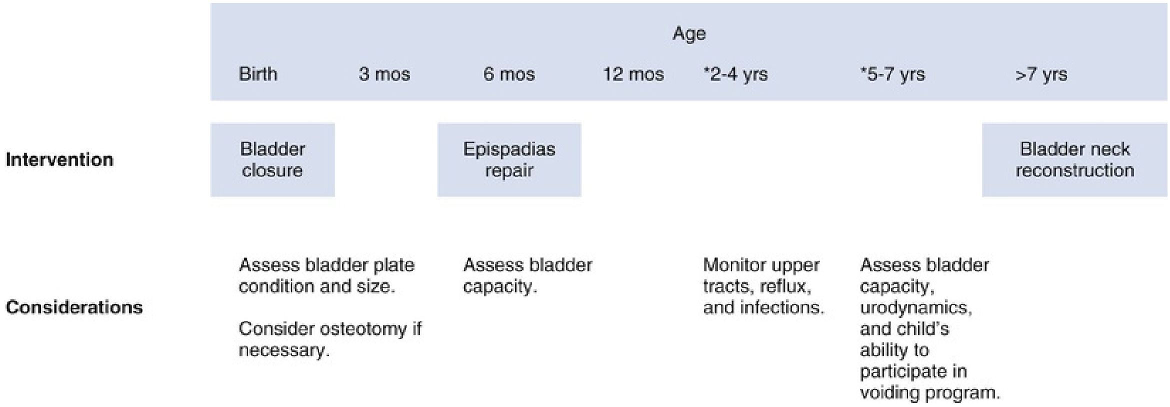
The findings in this series were that continence was more likely in patients who underwent primary exstrophy closure before 72 hours of age or after 72 hours of age with an osteotomy. These results coincide with those of Husmann et al. (1989a), who found that patients who underwent delayed closure without osteotomy showed a continence rate of only 10%. There was another revealing factor in this study. Bladder capacity at the time of bladder neck repair gave a strong indication of not only who would be dry but also who would be dry sooner. If the patients were divided into those with a preoperative bladder capacity greater than or less than 100 mL, results showed that the group with the larger capacity had a high rate of continence: 42 of 50 dry and voiding versus 5 of 17 in the lower-capacity group. In addition, the mean times to dryness in the higher- and lower-capacity groups were 10 months and 21 months, respectively (14 months in the group overall).

In a similar series by Purves et al. (2008), the results in females mirrored those of the male group, with a slightly higher continence rate of 74% (dry day and night) and social continence again in 10%. Again, patients with capacity greater than 100 mL had better outcomes. In a phenomenon not seen in the males, 6 patients (20%) became continent after bladder and pelvic closure alone.

A continence procedure should be delayed until the bladder reaches a capacity of 100 mL and the child is motivated to be dry and participate in a postoperative voiding program. The vast majority achieve daytime dryness within 12 months after bladder neck repair. A few patients gain a longer daytime dry interval during the second year after their outlet procedure. However, patients who are not dry within 2 years are considered incontinent, and the procedure is considered to have failed. The onset of nighttime continence varies from 2 to 3 years and takes longer than the time needed for daytime continence. Caione et al. (1999) showed that use of desmopressin acetate (DDAVP) can increase the onset and number of dry nights in these patients. In the series by Baird et al. (2007), 25% of patients required either DDAVP or oxybutynin to establish nighttime dryness.

Urodynamic evaluation by Dave et al. (2001) showed that patients with good continence after bladder neck repair had high cystometric bladder capacity and compliance compared with those who were incontinent. However, unstable contractions were seen in both groups. Also, higher end filling pressures were reported, and those patients had a high incidence of nonobstructive hydronephrosis. These findings, in addition to those of Bolduc et al. (2002), indicate that careful lifelong follow-up is essential in these patients after successful childhood reconstruction.

From diagnosis and primary closure to bladder neck repair for urinary continence, the management of bladder exstrophy courses over years with a number of diagnostic and therapeutic procedures. Fig. 31.26 displays a summary of the timeline for bladder exstrophy repair.



Age
Birth
3 mos
6 mos
12 mos
*2-4 yrs
*5-7 yrs
>7 yrs
Intervention
Bladder closure
Epispadias repair
Bladder neck reconstruction
Considerations
Assess bladder plate condition and size.
Consider osteotomy if necessary.
Assess bladder capacity.
Monitor upper tracts, reflux, and infections.
Assess bladder capacity, urodynamics, and child's ability to participate in voiding program.

FIG. 31.26 Timeline for exstrophy reconstruction. *The authors recommend yearly cystogram and cystoscopy to monitor bladder growth.

Key Points: Preparation for Continence Procedure in Bladder Exstrophy

- Bladder capacity of >100 mL (minimum)
- Stable urodynamics
- Child is motivated and ready to participate in a voiding improvement program.
- Exposure to voiding improvement program 6 months before bladder neck repair
- Evaluation by child psychologist with a background in pediatric urology

Other Modern Exstrophy Repairs: Continence Outcomes

Schrott-Erlangen Approach

Rosch et al. (2001) have reported on 100 patients, using this technique in newborns and failed closures: 91 children with exstrophy (69 boys and 22 girls) and 9 with complete epispadias (7 boys and 2 girls) have had this procedure performed. The complete single-stage repair was performed in 47 children and included pelvic closure without osteotomy, bladder neck reconstruction, an antireflux procedure, and epispadias repair using the Cantwell-Ransley technique. An additional 53 patients underwent primary reconstruction elsewhere and then had bladder neck reconstruction and epispadias repair performed. Continence was defined as dryness for more than 3 hours and no nocturnal enuresis. Partial continence was defined as dryness for 1 to 3 hours, or for longer than 3 hours with occasional stress incontinence or wet nights. Patients dry for less than 1 hour were considered incontinent. Among the patients undergoing single-stage repair, 34 of 39 are dry (72%) and voiding per urethra, 2 of 39 are on clean intermittent catheterization (CIC), and 3 of 39 are on CIC after augmentation; 4 patients are partially continent and 2 are dry on desmopressin. Four patients are incontinent and 3 have undergone continent diversion. Of 53 patients who underwent primary closure elsewhere, 55% are continent and 7 have been augmented; 14 are partially continent and 10 are incontinent, 4 of whom have undergone continent diversion.

Complete Repair

Various series have been published about outcomes, including the need for ureteral reimplantation in the first year of life, the number of patients requiring hypospadias repair after this procedure, and the complication rates of this procedure. However, little has been published about the long-term continence results or the need for bladder neck reconstruction in this group of patients. Borer et al. (2005) reported that ultimately almost 65% to 70% of patients undergoing CPRE in the newborn period require a bladder outlet procedure. In an updated series, Gargollo et al. (2011) found that 80% of patients with long-term follow-up required bladder neck repair. In a series by Hafez et al. (2005) with some patients who had delayed or failed primary closures, 84% of males and 50% of females required bladder neck repair to be dry. Some of these required concomitant bladder augmentation to be dry. In another large series by Shoukry et al. (2009), no patients were continent after CPRE alone and most required augmentation to be dry. More important, early dry intervals *did not* translate into later continence.

Shnorhavorian et al. (2008) reviewed their experience with 39 patients older than 19 years with CPRE. Daytime voided continence was achieved in 74% of males and females with 4 years of follow-up. However, only 20% and 43% of boys and girls, respectively, achieved continence without the need for bladder neck repair; 18% achieved dryness with bladder neck injection only. In a recent large series of CPRE patients referred for reclosure or after successful closure for bladder neck reconstruction, the results were interesting (Schaeffer et al., 2011). All patients were operated on by an experienced senior surgeon who does not do CPRE in newborns. None of the 14 referred patients who underwent successful CPRE in the newborn period was continent for any appreciable interval after closure. Of the 19 patients who underwent bladder neck reconstruction after complications with their newborn closure, only 25% were voiding from the urethra and continent. In the group with a successful primary closure (n = 14), 57% were dry day and night and 28% were dry during the day only (Schaeffer et al., 2011). Of major interest, all patients who were dry after bladder neck reconstruction had a successful primary closure with pelvic osteotomy and hypospadias repair before 1 year of age, and none required ureteral reimplantation before bladder neck repair. These data clearly show that in the majority of cases “complete repair” patients need to undergo bladder neck repair. However, as in all of the major repairs, a successful primary closure with fewer bladder violations and interval surgeries will increase the chance for bladder growth and voided continence. In a recent study, Di Carlo et al. (2018) reported an expanded series of bladder neck reconstructions in patients who underwent an outlet procedure after a successful primary closure without complications; 60% were dry during the day and night, 25% remained totally incontinent, and 11% were dry during the day only. All had an osteotomy at birth, early hypospadias repair, and no ureteral reimplantation during infancy. Long-term data seem to suggest that an older age may also favor continence outcomes (Ellison et al., 2016).

Other methods have combined epispadias repair with bladder exstrophy closure in the male patient. In a series of 38 boys with classic exstrophy, Baird et al. (2005c) evaluated patients with either failed or delayed primary closures. The complications were those seen with routine exstrophy repairs including urethrocutaneous fistula, urethral strictures, and so on. Three boys were dry with combined closure alone. Nineteen boys went on to modified Young-Dees-Leadbetter bladder neck repair; 12 (63%) of these 19 were totally dry day and night. These data as well as the data of Mitchell and Grady clearly show that epispadias repair and exstrophy closure can be combined with acceptable results. However, the complications are real and can portend the loss of any chance at volitional voiding, and the procedures should be performed only by experienced exstrophy surgeons and not the occasional surgeon. The combination of the epispadias repair may also pose the unique complication of ischemic penile loss in the form of total glandular and corporal loss, hemiglans loss, corporal atrophy, or hemiglans and corporal loss (Schaeffer et al., 2011).

Kelly Repair

There are few papers with long-term follow-up of the Kelly technique. However, a recent presentation by the Melbourne group gives the best and most current results that can be found with this repair (Jarzebowski et al., 2009). Data were collected in children older than 4 years. Complete continence was defined as dryness for longer than 3 hours day and night (with 2 or fewer wet nights per month). Partial continence was dryness for 2 or more hours during the day and 3 or more wet nights per month and/or stress incontinence. Of 31 patients on whom the Kelly technique was used, 24 void spontaneously and 17 of 31 void in an unaided fashion (without intermittent catheterization or augmentation); 3 of 17 (18%) were voiding in an unaided fashion and had complete continence, and 9 of the remaining 17 (53%) had partial continence. The 18% dry and voiding rate compares favorably with that recently reported for CPRE. Another study from Italy (Berrettini et al., 2009) showed that in 5 of 9 boys, continence was achieved with a Mainz pouch in 1, intermittent catheterization in 2, and by voiding in 2; 1 of 9 experienced glans loss (Berrettini et al., 2009).

Exstrophy Reconstruction Failures and Complications

Failed Closure

After any form of repair, failures can manifest as complete bladder dehiscence, bladder prolapse, neourethral stricture and obstruction, soft-tissue loss, and vesicocutaneous fistula (Fig. 31.27) (Massanyi et al., 2013). Meldrum et al. (2005) reported on a select group of children in whom exstrophy reconstruction had failed before referral to a tertiary care facility. In the cohort of 101 children, 51 had primary surgical management performed by a fellowship-trained pediatric urologist, 18 by a general urologist, 6 by a pediatric surgeon, and 9 by an unknown surgeon. After successful reclosure, 38 patients eventually developed adequate bladder capacity for bladder neck reconstruction, and only 26% (10) eventually achieved dryness. These data emphasize the need for initial successful reconstruction and suggest that individuals undertaking this reconstruction should be comfortable with the complexity of repair. It is prudent for the surgeon who may see only a few patients with this condition to consider referral of these complex management situations to a center staffed by professionals with special expertise and experience.

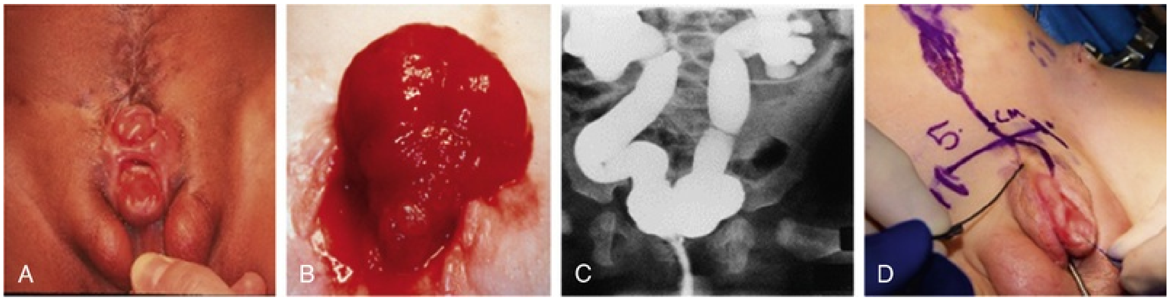


FIG. 31.27 Examples of failed bladder exstrophy closures. (A) Bladder prolapse; (B) bladder dehiscence; (C) outlet obstruction; (D) vesicocutaneous fistula. A combination of these, or any complication that necessitates a repeat closure, would also define a failed bladder closure.

In a large series by Schaeffer et al. (2008), 185 patients who underwent closure by 1 of 2 surgeons were reviewed for major and minor complications (Table 31.4). Sixty-three underwent osteotomy at the time of primary closure.

There were 14 major complications (11%) and 27 minor complications (14%). Major urologic complications included bladder prolapse or dehiscence in 6 male patients (3%), all of whom underwent successful reclosure. Major orthopedic complications, including nonunion in 2 patients, leg-length inequality in 1, and persistent joint pain in 1, developed in 4 of 63 patients (6%) who underwent osteotomy. Major neurologic complications included femoral nerve palsy in 4 of the 185 patients (2%). There were 21 minor urologic complications (11%), including posterior bladder outlet obstruction in 4 patients, urethrocutaneous fistula in 2, suprapubic tube removal in 2, intrapubic stitch erosion in 4, febrile urinary tract infection in 6, and surgical site infection in 3. Six patients (3%) had minor orthopedic complications, including pelvic osteomyelitis in 1, pin site infection in 3, and a pressure sore from immobilization in 1.

TABLE 31.4

Urologic, Orthopedic, and Neurologic Complications in 185 Primary Bladder Closures

UROLOGIC COMPLICATIONS	**NUMBER**
Bladder prolapse/dehiscence	6
Postoutlet obstruction	4
Suprapubic tube removal	2
Intrapubic stitch erosion	4
Febrile urinary tract infection	6
Wound infection	3
Bladder calculi	5
ORTHOPEDIC COMPLICATIONS	
Nonunion osteotomy	2
Leg length inequity	1
Persistent joint pain	1
Pelvic osteomyelitis	1
Pin site infection	3
Pressure sore	1
NEUROLOGIC COMPLICATIONS	
Femoral nerve palsy	4

Dehiscence, which may be precipitated by incomplete mobilization of the pelvic diaphragm and inadequate pelvic immobilization postoperatively, wound infection, abdominal distention, or urinary tube malfunction, necessitates a 4- to 6-month recovery period before a second attempt at

closure can be made (Gearhart and Jeffs, 1991a; Gearhart et al., 1993b) (Fig. 31.28A1). Dehiscence and prolapse after CPRE have also been reported and may be associated with glans, corporeal, urethral plate, and other major soft-tissue loss (Figs. 31.28B and C). Tension-free reclosure with osteotomy and immobilization are important factors in initial and subsequent closures. Unfortunately, the chance of obtaining adequate bladder capacity for bladder neck plasty and eventual continence after multiple closures is markedly diminished (Gearhart et al., 1996a; Novak et al., 2010). Similarly, bladder prolapse is considered a failure and requires bladder reclosure or revision. In a recent series from a single institution of 122 patients who underwent reclosure with a mean follow-up of 14 years, the voided continence rate was 16% (Novak et al., 2010). In a patient with significant bladder prolapse or dehiscence, at the time of secondary closure we combine epispadias repair with bladder, posterior urethral, and abdominal wall closure (Gearhart et al., 1998). The patient is given testosterone enanthate intramuscularly 5 weeks and 2 weeks before surgical repair and undergoes an osteotomy with concomitant bladder, urethral, and abdominal wall closure. Major soft-tissue loss that is seen after CPRE necessitates extensive preoperative planning; use of buccal mucosal or full-thickness grafts and tissue expansion may be required before definitive surgery (Gearhart and Baird, 2005).

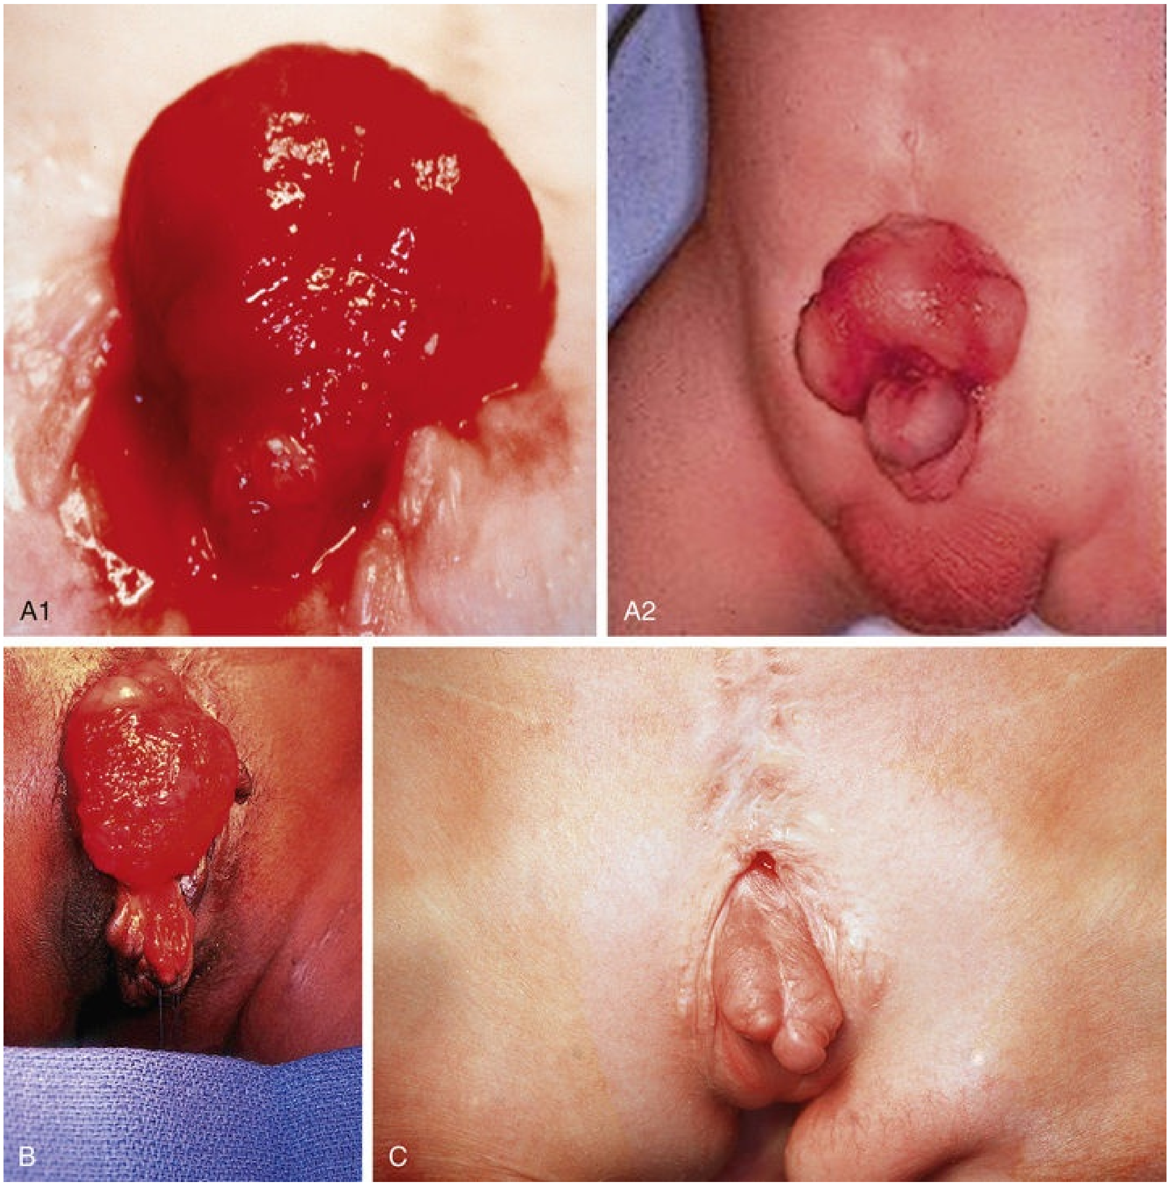

FIG. 31.28 (A1) Failed female newborn closure. (A2) Major bladder prolapse after CPRE without osteotomy. (B) Complete dehiscence and loss of right glans and partial loss of corpora after CPRE repair. (C) Loss of right glans and urethra after penile disassembly in newborn (under testosterone stimulation before placement of full thickness skin graft).

Baird et al. (2005c) reported on 38 boys undergoing combined exstrophy closure and epispadias repair along with osteotomy; in 30, prior reconstruction had failed. Complications in this group were limited to urethrocutaneous fistulae and urethral strictures. Although the results after reclosure are not as good as those obtained with a successful primary closure, they are respectable and may obviate the need for bladder augmentation.

Neourethral stricture is often associated with paraexstrophy skin flap use, pubic suture reaction, erosion, or the use of urethral stents. This may be somewhat subtle; however, warning signs consist of UTIs, detectable increased bladder volumes on ultrasonography, bladder stones, prolonged dry intervals, and unexplained rectal prolapse. In a review by Baker et al. (1999), posterior urethral obstruction was found in 41 patients. Most episodes occurred within 60 days after primary closure. If diversion was used for longer than 6 months, the ultimate fate of the bladder was augmentation. If diversion was used for less than 6 months, most reconstructions were ultimately bowel free. The authors have also seen outlet obstruction, including complete obliteration after the CPRE and Kelly repair (Hernandez et al., 2008). Whether this is a result of ischemic damage to the urethral plate or technical error is unclear. Regardless, because there is a paucity of long-term data from these two repairs, the outlet must be monitored carefully as with all exstrophy patients after primary closure. Ultimately, posterior urethral obstruction after exstrophy closure markedly decreases the success of any repair. This complication presents a significant risk to the upper urinary tract and should be detected early.

Although all closed exstrophy bladders have vesicoureteral reflux, upper tract deterioration is the ultimate fate of significant outlet obstruction. At this point the management includes urethral dilation (incision), open urethroplasty, or upper tract diversion. If renal function is compromised, the choice must achieve unquestionable free drainage to allow the upper tracts and kidneys to recover fully. Further bladder neck or urethral reconstruction should not be performed until the posterior urethral stricture is clearly repaired and free drainage has been achieved. After CPRE repair, up to 50% of patients require bilateral ureteral reimplantation during the first year after surgery because of UTIs and increasing hydronephrosis.

Massanyi et al. (2012) found that a large number of patients with a vesicocutaneous fistula after primary closure actually have a failed closure. On evaluation 13 of 18 patients referred because of vesicocutaneous fistulae were found to have a failed closure represented by (1) a fistulous tract in the lower abdominal midline; (2) a pubic diastasis increased from preclosure measurements; and (3) cystoscopic evidence of an anteriorly positioned bladder just beneath the abdominal skin.

Despite satisfactory closure, some bladders never achieve adequate capacity to act as functional bladders. Baradaran et al. (2011) presented a large series of patients including those with failed primary bladder closures (n = 62) who underwent successful secondary closure; these patients were evaluated and compared with another group of patients with successful primary closures (n = 48). Both groups were followed over 5 years. Bladders in patients who had had a successful primary closure had a significantly larger cystographic capacity than the group with failed closure. Bladders grew at a significantly slower rate in the group with failed procedures and had significantly lower bladder capacities over time. These data underscore the importance of a successful primary closure. It has become clear that multiple bladder closures, bladder prolapse, dehiscence, bladder calculi, recurrent infections, and vesicostomy have a negative impact on the potential of the exstrophy bladder (Silver et al., 1997b).

Unsuccessful primary closures regardless of the method of repair really calls into question the ability of the bladder to grow, undergo an eventual bladder neck reconstruction, and be continent of urine. Schaeffer et al. (2011) reported on a large series of patients with failed CPRE procedures who were referred for further treatment. Of the 23 male patients, only half obtained a capacity sufficient for a bladder neck procedure, and only 25% were voiding and continent. Novak et al. (2010) reported a very large series of 122 patients with a failed primary or secondary closure of whom 94 underwent a successful repeat closure. Only 38 were candidates for bladder neck repair and only 17 of the 94 (18%) were voiding and continent. Thus, regardless of the type of repair, a failed closure portends significant implications for long-term surgical outcomes.

We have used transurethral injection of collagen and dextranomer around the bladder neck to increase outlet resistance and stimulate the bladder to grow after successful reclosure. However, in our hands this has not been as successful as reported by Caione et al. (1993a, 1993b). If the bladder does not grow to a sufficient size for bladder neck reconstruction, bladder augmentation is recommended in this situation. If the bladder neck or urethra or both are problematic, a catheterizable continent stoma with or without bladder neck plasty or transection is performed, along with augmentation (Gearhart et al., 1995b).

Further ramifications include the financial burden outside the obvious costs of a repeat closure (Hesh et al., 2016). That is, a failed primary closure may cost the patient and their family an additional $19,677 in total hospital fees during a year of follow-up, with associated professional fees of more than $24,000.

Key Points: Evaluation of a Failed Closure

- Quality of the bladder template
- Perivesical and periurethral scarring
- Pelvic diastasis
- Prior pelvic osteotomy
- Minimum of 4 months delay since failure (Kasprenski et al., 2018)

Failed Bladder Neck Repair

Even with experienced exstrophy surgeons, missteps can occur, and there remains a subgroup of children with urinary incontinence after bladder neck reconstruction secondary to (1) inadequate outlet resistance; (2) a small bladder capacity (lack of growth after bladder neck reconstruction); (3) decreased compliance; or (4) a combination of these factors.

If urinary continence, defined as a 3-hour dry interval, is not achieved within 2 years after bladder neck reconstruction, failure to achieve dryness has resulted. Occasionally the dry interval is nearly acceptable for daytime dryness (i.e., longer than 2 hours). In these situations urethral bulking agents have been used in an attempt to avoid further major reconstructive procedures (Burki et al., 2006a). Formerly, collagen was the bulking agent of choice, but often multiple injections were required (Ben-Chaim et al., 1995a). In a large series from Paris, Lottmann et al. (2006) reported on the use of a dextranomer-based bulking agent in childhood with incontinence from multiple causes. Twenty-six patients had the exstrophy-epispadias syndrome. Of the 9 exstrophy patients, 4 achieved success; in the epispadias group the success rate was much higher (longer than 3 hours dry by intermittent catheterization or voiding).

In a recent large series of specifically exstrophy-epispadias patients (Shah et al., 2014b) with a median follow-up of 8 years, 41 underwent injection before bladder neck reconstruction and 25 after bladder neck reconstruction. Injection before bladder neck reconstruction did result in 50% developing an adequate capacity for bladder neck reconstruction, but only 9 (22%) became dry. Bladder capacity was the most predictive variable of a successful bladder neck reconstruction after bladder neck injection. In the group of 25 patients with prior bladder neck surgery of whom 16 were partially dry (1 to 3 hours), all were rendered socially continent (dry for longer than 3 hours) after bladder neck injection. Of the 9 dry for less than 1 hour, bladder neck injection was not helpful at all. **Thus outlet injection after a failed bladder surgery is more**

successful if a reasonable dry interval has been achieved with open bladder neck surgery. In recent data from Alova et al. (2012), bladder neck surgery after prior dextranomer bladder neck injection was not found to be more difficult and success rates were acceptable with long-term follow-up. However, repeated dextranomer injections after a prior failure did not result in success. Currently, a major NIH approved Phase 1 study using the patients' own harvested myoblasts grown in the lab and reinserted into the bladder neck to achieve dryness after failed bladder neck surgery is ongoing (ClinicalTrials.gov, NCT01011777).

Some successes have been seen with repeated Young-Dees-Leadbetter repair if the bladder neck is patulous, the bladder capacity is adequate, and urodynamic evaluation reveals a stable bladder (Gearhart et al., 1991a). In that series only 50% of patients with a failed prior bladder neck reconstruction were candidates for reoperative surgery. In this highly select group, continence rates were acceptable after reoperative bladder neck reconstruction. All of these patients had excellent bladder capacity (>100 mL) and were stable on urodynamics before the redo repair. A majority of bladder neck failures require eventual augmentation or continent diversion (Burki et al., 2006b). The artificial urinary sphincter has been used with some success in patients who have a good bladder capacity. However, in most of these failures the bladder capacity is small and augmentation is required. At the time of reoperative surgery, either the bladder neck is transected proximal to the prostate with a Mitrofanoff substitution or a continence procedure, such as creation of an artificial sphincter, is performed. In our extensive experience with failed bladder neck reconstructions, most of the patients have had several surgeries of the bladder neck area and are desperate to be dry. In a recent large series of 31 patients who had undergone prior bladder neck reconstruction, Novak et al. (2009) found that most patients had undergone multiple prior repairs to achieve continence. Bladder neck transection along with enterocystoplasty was performed with initial continence achieved in 86%. Seven patients underwent further bladder neck surgery, and 90% achieved dryness by intermittent catheterization. One renal unit was lost, nonobstructive hydronephrosis developed in 8, and bladder stones occurred in 30%.

Delayed urinary continence has been reported at the onset of puberty in some males, and this has been attributed to prostatic growth. On MRI, the prostate of exstrophy patients is cloverleaf shaped and absent anteriorly, and its mean weight and maximal cross section and volume are normal (Gearhart et al., 1992). Therefore it is doubtful that growth of this abnormally configured prostate can have much impact on urinary continence after failed bladder neck repair, and improved continence at puberty may be a result of changes in the pelvic floor with maturity.

Key Points: Evaluation of the Failed Bladder Neck Reconstruction

- Bladder capacity under anesthesia
- Stable urodynamics
- Re-evaluation by voiding improvement program
- Re-evaluation by child psychologist

Failed Genitourethral Reconstruction

Common complications of modern epispadias repair include urethrocutaneous fistula formation. This has been reported in as few as 4% and as many as 19% of cases (Kajbafzadeh et al., 1995; Surer et al., 2000). Urethral tortuosity with difficult catheterization or strictures are uncommon with modern epispadias repair. Since the application of the penile disassembly for epispadias reconstruction, newer, more significant complications have been noted (Hammouda, 2003). Gearhart and Baird (2005) have reported loss of the glans, corpora, or both in addition to loss of penile skin and the urethral plate (see Fig. 31.28C). Whether this is secondary to surgical misadventure, vagaries in the blood supply of the penis, or the intrinsic difficulties in the procedure remain a topic of debate. Reconstruction of these complications has required additional techniques, including tissue expansion, full-thickness skin grafting, buccal mucosal grafting, and other complex techniques. In some patients with significant losses, neophalloplasty may eventually provide the material for final cosmetic reconstruction. Recent data by Massanyi et al. (2012) show the applicability of radial forearm phalloplasty in patients who have lost glans, corpora, and other soft tissue as a consequence of epispadias repair or in cloacal exstrophies where penile tissue hardly exists. This alternative allows a sensate cosmetic neophallus for this special group of exstrophy failures.

At an older age, unsightly penile scars and a short phallus may prompt further surgical intervention. Scar excision can be closed in a plastic fashion if enough penile skin is available. Otherwise, flaps or full-thickness skin grafts can be used. In severe cases, tissue expanders can be placed under the penile skin and gradually inflated over 6 weeks to allow more penile skin and obviate the need for grafting. Freeing all scar tissues and suspensory ligament tissue can maximize available penile length. A dorsal dermal corporeal graft or ventral corporeal plication or rotation may also help lengthen as well as correct any chordee. However, it must be recognized that the exstrophy penis, when compared with age- and race-matched controls, is congenitally deficient in anterior corporeal tissue as assessed by MRI (Silver et al., 1997b). Therefore overly aggressive attempts at penile lengthening may result only in corporeal denervation and devascularization without additional lengthening.

Alternative Techniques of Reconstruction

Not all children with bladder exstrophy are candidates for primary repair at initial evaluation because of a small bladder plate or significant hydronephrosis. Additional reasons for seeking other methods of treatment include failure of initial closure with a small remaining bladder or failure of continence surgery, or both. Excluding the patients in whom initial treatment fails, this discussion deals with options available when modern repair is not chosen by the surgeon or for other reasons has not been suitable.

Ureterosigmoidostomy

Whichever urinary diversion is chosen, the upper tracts and renal function are initially normal. This allows the reimplantation of normal-sized ureters in a reliable, nonrefluxing manner into the colon or other suitable reservoir. Historically, ureterosigmoidostomy was the first form of diversion to be popularized for patients with exstrophy. Although the initial series was associated with multiple metabolic problems, results improved markedly with newer techniques of reimplantation (Koo et al., 1996; Zarbo and Kay, 1986). Ureterosigmoidostomy is favored by some because of the lack of an abdominal stoma. **However, this form of diversion should not be offered until anal continence is normal and after the family has been made aware of the potential serious complications, including pyelonephritis, hyperkalemic acidosis, rectal incontinence, ureteral obstruction, and delayed development of malignancy** (Duckett and Gazak, 1983; Spence et al., 1979). More recently, ureterosigmoidostomy has been proposed again as an initial treatment of bladder exstrophy with acceptable continence and renal preservation on follow-up of 10 years or longer. In a long-term Swiss study by Gobet et al. (2009) of 42 patients, 50% had their ureterosigmoidostomy in place and were fecally continent at 50 years of age. One had developed a colonic malignancy and 60% had normal renal function. Another study from Sweden by Pettersson et al. (2013) found a higher rate of colorectal cancer than the Swiss study and a higher rate of rediversion. The mean time from ureterosigmoidostomy was 38 years. Almost all of the malignancies were poorly differentiated adenocarcinoma. The difference in the results of these two European studies is unclear but underscores the need for lifelong vigilance for early detection of cancer (Honeck et al., 2017).

Stein et al. (1999) treated a group of 128 patients with bladder exstrophy-epispadias with the Mainz technique for ureterosigmoidostomy. The Mainz Sigma pouch is constructed and the ureters reimplanted in a nonrefluxing manner. The abdominal wall is reconstructed and the bladder is closed as a seminal receptacle above the prostate. The penis is then reconstructed at a later date. D'elia et al. (2004) reported on 26 patients with the exstrophy-epispadias complex who showed excellent continence rates with long-term upper tract preservation when compared with standard ureterosigmoidostomy. Continence was achieved in 95% of patients with a rectal reservoir. Their recommendation for treatment in a number of patients with severely impaired renal function was that a colonic conduit was the best method of choice for diversion. In the patients with a normal or slightly dilated upper tract and intact anal sphincters, a Mainz rectal reservoir was recommended. Although the group from Mainz reported no cancer in a long-term follow-up study of patients who underwent ureterosigmoidostomy, the risk for malignancy still exists. Patients who have had mixing of urine and feces at any time during reconstruction remain at high risk for the development of cancers (Smeulders and Woodhouse, 2001). Bladder exstrophy patients in whom an initial reconstruction has failed and who have polyposis at the time of repeated closure may also be at higher risk for the later development of malignancy (Novak et al., 2005). This is especially true in today's mobile society, in which careful long-term follow-up may be difficult to guarantee. All patients with a ureterosigmoidostomy should have a yearly renal ultrasound and colonoscopy in adult life.

Continent Urinary Diversion in the Exstrophy Patient

In modern pediatric urology there is usually little need for incontinent urinary diversion in the patient with bladder exstrophy. In a young child with a bladder that is too small to close, or in a failed closure where the bladder template is too small to reclose, we recommend a nonrefluxing colon conduit. This protects the kidneys from vesicoureteral reflux, and undiversion can be performed when clinically indicated at an older age.

Advances in the reconstruction of the lower urinary tract in the past several years have been applied to the patient with exstrophy (Cervellione et al., 2008). Most commonly, further reconstruction is required in the patient in whom bladder neck reconstruction has failed. If a patient does not meet the criteria for bladder neck reconstruction (i.e., inadequate bladder capacity or inability to conform to a voiding regimen), deferring surgery is advisable. Patients in whom bladder neck reconstruction fails are most often destined to augmentation cystoplasty and continent urinary diversion. Surer et al. (2003) reported on 91 patients with the exstrophy-epispadias complex who underwent continent urinary diversion. The majority had undergone prior failed bladder neck reconstruction (n = 62). Seventy-nine patients (87%) had exstrophy closure before referral, 53 also underwent bladder neck reconstruction, and 29 patients had never reached adequate capacity for bladder neck reconstruction. Ten of the 53 patients underwent one prior attempt, 35 underwent two prior attempts, and 8 underwent three prior attempts at bladder neck reconstruction. A combined augmentation cystoplasty, continent urinary diversion, and bladder neck closure was performed in 59 patients (65%), and reaugmentation and continent urinary diversion was performed in 18 children. Ileocystoplasty was used in 41 patients, and sigmoid cystoplasty was performed in 30 patients. The appendix was used as the continent channel in 67 patients. Continence using intermittent catheterization through the stoma was achieved in 93% of children with the most common complication reported being that of bladder stones, noted in 26%. Although infrequent, failures can occur with continent urinary diversion in exstrophy (Frimberger et al., 2003). The most common modes of failure were a deintussusception of a nipple valve, inadequate tunnel for an appendiceal channel, or continued bladder neck incompetence. The vast majority of these complications can be successfully repaired. Equally successful outcomes have been reported by Baird et al. (2005a) in adolescents who had undergone a mean of eight prior procedures before their definitive repair.

Occasionally, urinary diversion must be established at a very young age (5 years or younger). The need for early diversion in exstrophy is mainly driven by upper tract changes and social factors and can be safe in younger children with a favorable continence outcome. In a recent study by Baradaran et al. (2012b), 19 patients underwent early diversion (14 continent, 5 incontinent). Of the group who underwent early continent diversion, 7 had an early desire to be dry; 4 had persistent severe hydronephrosis; 1 had severe recurrent pyelonephritis; 1 underwent a repeat continent urinary diversion; 1 had inaccessible proper follow-up; and only 2 had a successful primary closure. Three patients had neobladder creation, 10 had augmentation with a continent stoma, and 2 had ureterosigmoidostomy. Currently, all patients with stomas are dry on intermittent catheterization. Continence can be achieved in most patients with exstrophy after failure of bladder neck reconstruction and is typically obtained through augmentation cystoplasty and closure of the bladder neck. If a patient is unlikely to develop adequate capacity for eventual bladder neck reconstruction, moving early to continent urinary diversion is preferable. One long-term concern has been the risk of malignancy in patients with continent urinary diversion. Recent data by Husmann and Rathbun (2008) revealed that the overall rate of malignancy is low unless associated with coexisting carcinogenic stimuli (prolonged tobacco, chronic immunosuppression) or the inherent risk associated with bladder exstrophy.

Key Points: Continent Urinary Diversion in the Exstrophy Patient

- Typically failed bladder closures that do not grow after reclosure
- Small newborns with bladders that do not grow after closure
- Bladders that do not achieve dryness or adequate capacity after bladder neck reconstruction
- Upper tract decomposition after bladder neck reconstruction or primary bladder closure

Transitional Exstrophy Patient: Adolescent and Adult Concerns

As children with exstrophy grow into adulthood, there is an increasing need to address long-term functional and psychological aspects of dealing with a multiorgan birth defect. Some aspects such as sexuality and continence are common to all forms of the exstrophy-epispadias complex; however, in cloacal exstrophy there are additional neurologic and orthopedic aspects that can lead to significant disability.

A mainstay of the functional reconstruction of the exstrophy-epispadias complex is the preservation of renal function. Functional reconstruction of the exstrophy-epispadias complex has been associated with good preservation of renal function (DeMaria et al., 1980; Schaeffer et al., 2013). Renal function, however, can be compromised after urinary diversion (Husmann et al., 1988). Although urinary diversion has been used successfully as a temporary modality for providing upper tract decompression (Baradaran et al., 2012b), most children eventually undergo undiversion to continent urinary pouches. Long-term urinary diversion is now infrequently used in the exstrophy-epispadias complex.

Continence

Early surgical management of patients with bladder exstrophy included initial cystectomy and replacement with an ileal conduit or ureterosigmoidostomy. The use of ureterosigmoidostomy has fallen into disfavor because of an increased identification of lethal colonic cancer (Gobet et al., 2009). Renal function, however, was preserved in the majority of patients with ureterosigmoidostomy. Some institutions have been using continent catheterizable pouches for bladder management (Nerli et al., 2008). More recently, however, use of augmentation cystoplasty with bladder neck reconstruction or closure has been used successfully to provide continence in the majority of patients (Kavanagh et al., 2012; Novak et al., 2009). Long-term concerns about augmentation cystoplasty continue to be raised. Fontaine et al. (2000) evaluated 53 patients who had undergone augmentation cystoplasty and had at least 10 years of follow-up. In 80% of patients, there was no reduction in GFR noted. Remediable causes were found to account for the reduction in GFR noted in the remaining 20% of patients, leading the researchers to conclude that augmentation cystoplasty was effective in providing urine storage without compromising long-term renal function. Because of the long-term potential for carcinogenesis in patients who had undergone ureterosigmoidostomy, concerns were raised regarding tumor formation in children with augmentation cystoplasty. **Husmann and Rathbun** (2008) **reviewed their experience with 153 patients who had undergone augmentation cystoplasty; 38 of these patients had bladder exstrophy, of whom 3 developed multifocal adenocarcinoma, which suggests that there may be an inherent risk for long-term carcinogenesis in patients with bladder exstrophy who undergo augmentation.** Exposure to cigarette smoking increased the potential for the development of cancers in patients with augmentation cystoplasty, as did the use of immunosuppression for post-transplant management. Endoscopic surveillance beginning 5 years after reconstruction has been suggested; however, identification of early lesions can be difficult in the augmented bladder. Fecal incontinence has recently been noted in patients with bladder exstrophy and appears to persist into adulthood (El-Hout et al., 2010). Although this has not been noted by other investigators, ongoing evaluation for this psychologically debilitating problem seems appropriate.

Male Concerns

Sexuality

The most often expressed male concerns relate to the length, appearance, and the axis deviation (chordee) of the penis noted with exstrophy. Functional penile length can be gained by degloving the penis and resecting all of the residual scar tissue and releasing any remnants of the suspensory ligaments. Skin coverage can be a significant problem after penile lengthening procedures. Use of tissue expansion permits local skin to be used for coverage; however, this will require preplanning. Placement of a tissue expander and subsequent expansion can take 4 to 6 weeks. If the penile skin is not ideal for expansion, full-thickness grafting is a suitable alternative (Hernandez et al., 2008). Residual dorsal chordee from childhood reconstruction is not uncommon. Grafts (dermal grafts, tunica vaginalis, human AlloDerm) can be used to lengthen the dorsal aspect of the penis. Our preference is human AlloDerm because it is readily available, durable, and easy to use. Because of its anatomy, the penis must be opened dorsally for one half of its circumference as described by Perovic and Djinovic (2008) to lengthen and straighten the penis. Early measurements and determinations from artificial erections must be adequate because after grafting, the artificial erections can leak saline through the suture lines and give misleading information about the adequacy of correction.

In the cloacal exstrophy patient, the corporeal structures can be very small, and the only option for a functional phallus would be reconstruction with flap phalloplasty (see previous). Retention of all of the present corporeal and glanular tissue permits a location for anchorage of the neophallus (Ballaro et al., 1999).

Sexual function and libido in exstrophy patients are normal (Woodhouse, 1998). The erectile mechanism in patients who have undergone epispadias repair appears to be intact: 87% of boys and young men in the Hopkins series experienced erections after repair of epispadias (Surer et al., 2000). Woodhouse (1998), Ben-Chaim et al. (1996), and Ebert et al. (2008) reported satisfactory orgasmic function in most patients. In the men who had participated in sexual intercourse, female partners also expressed sexual satisfaction. In the series by Ben-Chaim, the only patients who had no ejaculation were 2 patients who had undergone cystectomy. A report from Castagnetti et al. (2010) of 19 men with bladder exstrophy evaluated via the International Index of Erectile Function questionnaire and compared with normal men indicated a higher incidence of erectile dysfunction (58%) as compared with the normal controls (23%). Erectile function was worse in those who had undergone multiple surgeries for treatment of incontinence. Orgasmic function was also noted to be lower in men with exstrophy. No difference in sexual desire, sexual satisfaction, or overall satisfaction was indicated, leading the authors to conclude that men with bladder exstrophy seem to lead a sexual life that is as satisfactory as that of their peers. Overall, it seems from the reports of many investigators that most men with exstrophy are able to achieve normal erectile function and are sexually satisfied. In a recent survey study by Baumgartner et al. exploring the long-term sexual health outcomes in men with bladder exstrophy it was found that 85% of respondents reported being sexually active in their lifetime, with an average Sexual Health Inventory for Men score as 19.8 (Baumgartner et al., 2017b). Of the patients 31 who had undergone semen analysis, only 4 had reported azoospermia.

As men grow into adulthood, additional concerns are now becoming evident and require transition of care to adult urology specialists. Men with bladder exstrophy will increasingly be seeking evaluation for prostatic hyperplasia and prostate cancer (Berkowitz et al., 2008). Silver et al. (1997a) reported on the ability to identify PSA in men with exstrophy. PSA was noted to be below the upper age-specific limit of norms, indicating that PSA changes could be muted in men with exstrophy. Routine digital rectal examination and PSA screening should become part of the standard follow-up for men with bladder exstrophy as with age-related screenings for normal men.

Male Fertility

Reconstruction of the male genitalia and preservation of fertility were not primary objectives in early surgical management of bladder exstrophy. Sporadic instances of pregnancy or the initiation of pregnancy by males with bladder exstrophy have been reported. In two large exstrophy series, male fertility was documented. Only 3 of 68 men in one study (Bennett, 1973) and 4 of 72 in another (Woodhouse et al., 1983) had successfully fathered children. Milking the urethra in an antegrade fashion from proximal to distal has provided pregnancy in some cases (Woodhouse, 1999). **In a large series of 2500 patients with exstrophy and epispadias** (Shapiro et al., 1985), **there were 38 males who had fathered children.**

Hanna and Williams (1972) compared semen analyses in men who had undergone primary closure and ureterosigmoidostomy. A normal sperm count was found in only 1 of 8 men after functional closure and in 4 of 8 men with diversion. The difference in observed fertility potential is probably attributable to iatrogenic injury to the verumontanum during functional closure or bladder neck reconstruction. Retrograde ejaculation may also account for low sperm counts after functional bladder closure. In a long-term study from our institution, Ben-Chaim et al. (1996) found that 10 of 16 men reported they ejaculated a few cubic centimeters of volume, 3 ejaculated only a few drops, and 3 had no ejaculation. Semen analysis was obtained in 4 patients: 3 had azoospermia and 1 had oligospermia. The average ejaculated volume of the patients who had sperm counts was 0.4 mL. In another large series by Stein et al. (1994) from Germany, the authors found that none of the patients who had reconstruction of the external genitalia could ejaculate normally, nor had they fathered children. Five patients who did not undergo reconstruction had normal ejaculation, and 2 had fathered children. The conclusion was that male patients with genital reconstruction and closure of the urethra demonstrated high risk of infertility. In a large study of successful primary closure from a large exstrophy center by Ebert et al. (2008), sperm parameters were poor in 18 of 21 patients, and follicle-stimulating hormone was increased in 25% of patients (Ebert et al., 2009). Ebert et al. (2010) reported on 17 adult men with bladder exstrophy undergoing the Erlangen approach single-stage procedure. At a mean follow-up of 19 years, 15 had bladder preservation and 12 were voiding per urethra; 16 men had proven ejaculation and 3 had normal sperm counts, 7 had oligoasthenospermia, and 6 had azoospermia. The potential for normal sperm counts was greater in patients who underwent only a single bladder neck procedure.

Assisted reproductive techniques have been applied to the exstrophy population (D'Hauwers et al., 2008). Regardless of the method of reconstruction of the external genitalia and bladder neck, newer techniques such as gamete intrafallopian transfer (GIFT) or intracytoplasmic sperm injection (ICSI) can be used to assist these patients in their goal of achieving pregnancy. Use of GIFT or ICSI in 21 men with exstrophy led to successful pregnancy with no instances of exstrophy in any of the offspring.

Female Concerns

Sexuality

The three main female concerns are the appearance of the external genitalia, adequacy of the vaginal opening, and uterine prolapse. Although initial correction of the female external genitalia defect is performed at birth, sometimes “touch-up” surgery must be performed at puberty. The appearance of the external genitalia is compromised because of the recurrence of the pubic diastasis, which leads to widening of the inferior abdominal scar and separation of the pubic hair. In addition, separation of the clitoral halves may be noted. To repair this in adolescence, mons flaps are raised laterally and brought to the midline and sewn to the fascia and themselves easily. In extreme cases with an extremely scarred flat mons veneris, tissue expanders can be placed laterally and gradually inflated over 6 weeks. These flaps are moved medially and used to reconstruct the mons. The pseudocapsules are rolled together in the midline to give the mons a more elevated appearance. Mobilizing lateral mons veneris flaps brings the clitoral halves closer to the midline and makes them easier to reconstruct into a single entity. Topical estrogen cream is used three times daily for 2 weeks before any external genital surgery to soften scars, increase skin viability, and improve local vascularity. The vaginal orifice is more vertical and somewhat stenotic in exstrophy compared with normal females (Cervellione et al., 2010). Insertion of tampons and sexual intercourse can therefore be difficult. Rotating an inverted U-flap of perineal skin into the incised posterior vaginal wall permits widening of the vaginal os (Stein et al., 1995). Uterine prolapse may be noted more frequently in women who have had vaginal wall cutback (Mathews et al., 2003a). After vaginal reconstruction, if the patient is not sexually active a vaginal dilator is used once daily until sexual activity occurs.

Uterine prolapse has been noted more frequently and at younger ages in girls with exstrophy-epispadias complex (Mathews et al., 2003a). Woodhouse (1999) reported prolapse in a number of patients, and it is a considerable problem to correct. Seven patients had total prolapse, one of whom had never had intercourse or a pregnancy. Woodhouse believes that prolapse may occur in up to half of patients after pregnancy. In a report from Mathews et al. (2003a), vaginal and uterine prolapse was noted commonly and even early in life (mean age 16 years). Uterine suspension provided only modest success for the prevention of recurrent prolapse. Stein et al. (1995), in a large exstrophy series from Germany, found that uterine fixation was required to correct prolapse in 13 patients with long-term follow-up of more than 25 years. The anterior displacement of the vaginal os and the marked posterior displacement of the puborectalis sling with its deficient anterior component were postulated as reasons for prolapse. Use of osteotomy has not been shown to reduce the incidence of uterine prolapse; however, the degree of pubic diastasis has been shown to be significant (Anusionwu et al., 2012). **The degree of prolapse depends on the degree of pubic bone divergence and the diameter of the opening in the levator hiatus for the vagina and rectum** (Miles-Thomas et al., 2006). We suspend the uterus to the sacrum with human AlloDerm or Pelvicol pubovaginal sling. The suspensory substance is sewn to the uterus from the cervix and dome of the uterus so that it can be snugly suspended to the ligaments on the front of the uterus. Regardless of the method of repair, the uterus must be anchored in such a way that it is fixated in the pelvis and less susceptible to prolapse.

Prophylactic suspension of the uterus in adolescent girls with exstrophy undergoing urinary reconstruction should be considered to prevent prolapse (Stein et al., 1999). Woodhouse (1999) believed that although prophylactic surgery may be helpful, once prolapse occurs, anterior fixation is insufficient to correct uterine prolapse in the exstrophy patient. Woodhouse recommends fixing both sides of the uterus from the cervix to the top of the uterus bilaterally to the presacral ligaments.

Mathews et al. (2003a) reported on a large series of girls and women with the exstrophy complex. All girls older than 18 years indicated that they had normal sexual desire, and many were sexually active. Mean age for commencement of sexual activity was 19.9 years. Although a few patients complained of dyspareunia, most indicated normal orgasms. Some patients indicated that they restricted sexual activity because of the cosmetic appearance of their external genitalia. Mons plasty is therefore important to obtain a cosmetically pleasing appearance either in infancy or in adolescence because hair-bearing skin and fat should be used to cover the midline defect. As mentioned earlier, we perform this procedure at the time of initial closure. It certainly can be done in adolescence with the use of rhomboid flaps, as popularized by Kramer et al. (1986).

Female Fertility

Krisiloff et al. (1978) reported on 45 women with bladder exstrophy who successfully delivered 49 normal offspring. The main complication after pregnancy was cervical and uterine prolapse, which occurred frequently. Burbage et al. (1986) described 40 women ranging from 19 to 36 years of age who were treated in infancy for bladder exstrophy; 14 pregnancies in 11 of these women resulted in 9 normal deliveries, 3 spontaneous abortions, and 2 elective abortions. Uterine prolapse occurred in 7 of the 11 patients during pregnancy. All had undergone prior permanent urinary diversions. Spontaneous vaginal deliveries were performed in those women, and cesarean sections were performed in women with functional bladder closures to eliminate stress on the pelvic floor and to avoid traumatic injury to the urinary sphincter mechanism (Krisiloff et al., 1978). With modern reconstructive techniques, successful pregnancies have been reported in female patients who have undergone continent urinary diversion (Kennedy et al., 1993). Giron et al. (2011) reported on 14 women who had undergone successful reconstruction and had 22 pregnancies. Seventeen pregnancies resulted in healthy newborns, 1 premature delivery of an infant who did well, 4 spontaneous abortions caused by genital prolapse, and 1 postpartum demise. After delivery, 3 mothers had temporary urinary incontinence, 1 mother had a vesicocutaneous fistula, and 7 women (50%) had genital prolapse.

In a larger report on 52 women with bladder exstrophy, Deans et al. (2012) reported on reproductive outcomes. Of those who attempted conception, 66% were successful; 19 patients conceived and there were 3 sets of twins—a total of 57 pregnancies. There were 34 of 57 live births (56%), 21 of 57 miscarriages (35%), 1 termination, and 4 stillbirths. There were 4 major complications related to delivery including 1 ureteral transection, 1 fistula formation, and 2 postpartum hemorrhages. In a recent survey study of 29 female exstrophy patients with continent urinary diversion, 12 (41%) of 29 respondents reported becoming pregnant. This resulted in 16 healthy newborns by elective cesarean section and one spontaneous abortion (Rubenwolf, Thomas et al., 2016). Deans et al. (2012) stress that pregnancy in women with bladder exstrophy remains high risk for the mother and the fetus and stress the need for referral to a tertiary care center for successful outcomes. In the majority of cases, planned cesarean section appears to be the safest mode for delivery.

Quality of Life

Overall and health-related quality of life (QoL) have become increasingly important as reconstructive techniques have improved and survival has become universal. Most groups have limited their studies to those with CBE. The preliminary results of the QUALEX (Quality of Life of Bladder Exstrophy) study (Jochault-Ritz et al., 2010) suggest that after reconstruction patients had reduced QoL. Adolescents reported a superior QoL score as compared with adults and children. Another report from Wittmeyer et al. (2010) of 47 patients (9 women and 16 men) also showed that QoL scores were less than norms; however, these reductions were mainly based on health concepts including limitation of physical activity and general health perception. Dodson et al. (2010) reported that overall adolescent QoL was comparable with norms, but parents reported significantly impaired adolescent general health and family activity and increased parental emotional distress. **Schaeffer et al.** (2013) **confirmed that adolescents with bladder exstrophy appear to have good QoL scores when compared with norms; although incontinent patients had a tendency to have lower QoL scores, the sample size evaluated was inadequate to demonstrate statistical significance.**

Long-Term Adjustment Issues

Interest has increased in long-term adjustment issues in patients with bladder exstrophy. Children with exstrophy undergo multiple reconstructive surgeries and have potential problems with respect to urinary incontinence and sexual dysfunction. However, the ultimate outcome would be better measured by how these children adjust overall in society. The severe nature of the exstrophy disorder could predict that this birth defect could have substantial psychological implications. Parental reaction to the child's medical condition may change the way the parents interact with the child. Incontinence may have a negative impact on social function and self-esteem. Multiple hospitalizations may interfere with the ability to be like other children. Concerning the potential medical and psychological implications of this anomaly, children born with exstrophy may be at increased risk for difficulties.

Formerly, there was a limited amount of information in the literature concerning this condition and its treatment and whether or not it has a deleterious effect on children and their families. Montagnino et al. (1998) evaluated younger children who performed more poorly and had disturbed behavior, specifically in skills related to function in school. Children who achieved continence after the age of 5 years were more likely to have problems with acting-out behavior. There were no differences in adjustment based on male or female sex, bladder versus cloacal exstrophy, type of continence strategy, or gender reassignment versus no reassignment. The conclusions of this long-term study were that children with exstrophy do not have clinical psychopathology (Montagnino et al., 1998). There was acting-out behavior rather than depression or anxiety, suggesting that improved outcomes may be achieved through a focus on normal adaptation rather than potential psychological stress. In addition, earlier achievement of continence through reconstructive efforts is potentially of psychological benefit.

This work was further supported by Catti et al. (2006), who found that QoL in adults was better in those who were continent with a good body image. More recently a large survey study demonstrated that patients with bladder exstrophy tend to have normative emotional and behavioral functionality, and expectantly, impaired functioning, such as internalizing symptoms of depression, anxiety or somatization was found in older patients (Hankinson et al., 2014). Moreover, males were liable to have higher rates of impairment compared with their female counterparts. Reiner (1999) studied 42 children with exstrophy and presented preliminary results suggesting that these patients tend to have more severe behavioral and developmental problems than children with other anomalies, significant body distortion, and self-esteem problems. Reiner has recommended early intervention with the exstrophy patient and family and continuation with long-term psychiatric support into adult life.

In a study from Europe, Feitz et al. (1994) found a more positive picture when they evaluated 11 women and 11 men with exstrophy, of whom 9 women (82%) and 10 men (91%) did not manifest any clinical levels of psychological stress. The authors concluded that these adults had a positive attitude toward life. With the use of structured instruments and appropriate evaluation and interviews, Reiner and Gearhart (2006) indicated that all 20 patients evaluated met criteria for at least one anxiety disorder. Older patients experienced waning of anxiety associated with peer discovery of incontinence after successful surgical reconstruction, and all noted intensified sexual activity with age. Data from Reiner et al. (2008) from a large series of male patients revealed that 14% experienced suicidal ideation. As they became older, 31% experienced this phenomenon; a few attempted adolescent or early adulthood suicide, and 1 succeeded. These findings underline the importance of screening patients for psychopathology as they age.

In an important study by Lee et al. (2006), females were found to have more close friendships, fewer disadvantages in relation to healthy peers, and more partnerships than males. There were no gender differences in adjustment within educational and professional careers, which overall were very good. Ebert et al. (2005) reviewed by questionnaire a group of 100 exstrophy adolescents. Education and social integration were high. All patients were heterosexual and almost 50% were sexually active, but almost 60% expressed anxiety about sexual activity. The most important finding was that 94% of patients expressed an interest in psychological assistance, underlining the importance of early childhood intervention.

Being born with exstrophy per se does not result in childhood psychopathology. Children with exstrophy exhibit some tendency toward increased problems with acting out or lack of attainment of age-appropriate adaptive behavior (Montagnino et al., 1998; Reiner, 1999). **Therefore early counseling should be part of the standard management strategy for all children with the exstrophy-epispadias complex.** In addition, patients and families should be encouraged to continue with psychological support as the child grows into adulthood.

Key Points: Bladder Exstrophy—Priorities in Management

- Size and quality of bladder template
- Extent of pubic diastasis and malleability of the pelvis
- Need for osteotomy
- Length and width of urethral plate
- Penile size
- Associated anomalies

Epispadias

Epispadias varies from a mild glanular defect in a covered penis to the penopubic variety with complete incontinence in males or females. It is most commonly noted as a component of bladder and cloacal exstrophy.

Male Epispadias

Isolated male epispadias is a rare anomaly, with a reported incidence of 1 in 117,000 males. Most male epispadias patients (about 70%) have complete epispadias with associated incontinence (Gearhart and Jeffs, 1998). Epispadias consists of a defect in the dorsal wall of the urethra. The normal urethra is replaced by a broad, mucosal strip lining the dorsum of the penis extending toward the bladder, with potential incompetence of the sphincter mechanism. The displaced meatus is free of deformity, and occurrence of urinary incontinence is related to the location of the dorsally displaced urethral meatus (Gearhart and Jeffs, 1998). The displaced meatus may be found on the glans, on the penile shaft, or in the penopubic region. All types of epispadias are associated with varying degrees of dorsal chordee (Fig. 31.29). In penopubic or subsymphyseal epispadias, the entire penile urethra is opened and the bladder outlet may be large enough to admit the examining finger, indicating obvious gross incontinence (see Fig. 31.1D). To a lesser extent than in those with CBE, patients with epispadias have a characteristic widening of the symphysis pubis caused by outward rotation of the innominate bones. This separation of the pubis causes divergent penopubic attachments that contribute to the short, pendular penis with dorsal chordee. Therefore the penile deformity is virtually identical to that observed in bladder exstrophy. The reported male-to-female ratio of epispadias varies between 3 : 1 (Dees, 1949) and 5 : 1 (Kramer and Kelalis, 1982a).

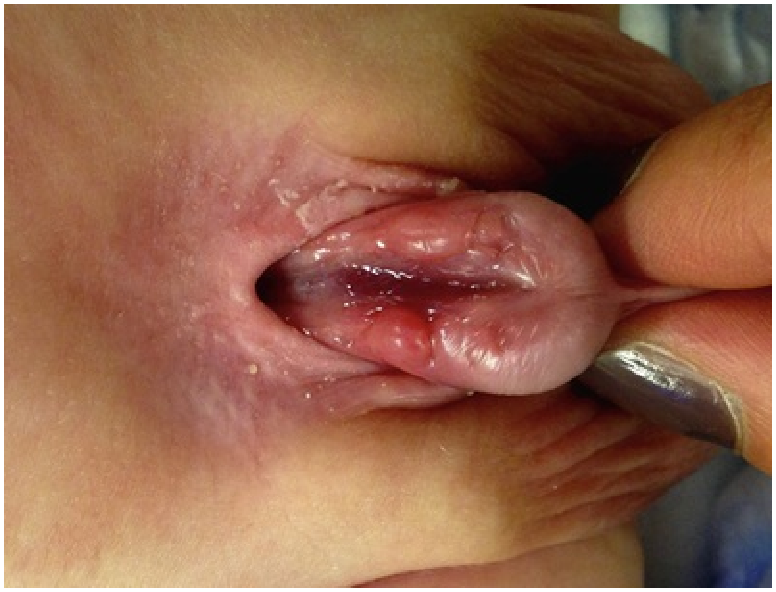

FIG. 31.29 Complete male epispadias.

Kramer and Kelalis (1982a) reviewed their experience with 82 male patients with epispadias. Penopubic epispadias occurred in 49 patients, penile epispadias in 21, and glanular epispadias in 12. Urinary incontinence was observed in 46 of 49 patients with penopubic epispadias, in 15 of 21 patients with penile epispadias, and in no patient with glanular epispadias. The goals of the treatment of complete male epispadias include creation of normal urinary control and establishment of a straight, cosmetically acceptable penis of adequate length that is functional for sexual intercourse.

Associated Anomalies

Anomalies associated with complete epispadias are usually confined to deformities of the external genitalia, diastasis of the pubic symphysis, and deficiency of the urinary continence mechanism. The only renal anomaly observed in 11 cases of epispadias was agenesis of the left kidney (Campbell, 1952). In a review by Arap et al. (1988), 1 case of renal agenesis and 1 case of ectopic kidney occurred among 38 patients.

The ureterovesical junction is inherently deficient in complete epispadias, and the incidence of reflux has been reported in a number of series to be between 30% and 40% (Arap et al., 1988; Kramer and Kelalis, 1982a). In a review by Ben-Chaim et al. (1995b) of a series of 15 patients with complete male epispadias treated at our institution, a lower rate of vesicoureteral reflux was noted compared with male patients with CBE (100% vs. 82%, respectively); the rate of inguinal hernias (33%) was also significantly lower. A possible explanation for the lower incidence of reflux in complete male epispadias is that the pouch of Douglas is not as enlarged and deep. Therefore the distal ureter enters the bladder in a more oblique fashion than in classic exstrophy (Gearhart and Jeffs, 1998).

Surgical Management

The objectives of repair of penopubic epispadias include achievement of urinary continence with preservation of the upper urinary tracts and the reconstruction of cosmetically acceptable genitalia. The surgical management of incontinence in penopubic epispadias is practically identical to that in closed bladder exstrophy.

Young (1922) reported the first cure of incontinence in a male patient with complete epispadias. Since this initial report, continence after surgical reconstruction has progressively improved (Arap et al., 1988; Burkholder and Williams, 1965; Kramer and Kelalis, 1982a; Mollard et al., 1998; Peters et al., 1988). In patients with complete epispadias and good bladder capacity, epispadias and bladder neck reconstruction can be performed in a single-stage operation. Urethroplasty formerly was performed after bladder neck reconstruction (Arap et al., 1988; Kramer and Kelalis, 1982a). However, improvements in bladder capacity in the small bladder associated with exstrophy (Gearhart and Jeffs, 1989a) and that associated with epispadias (Peters et al., 1988) have led us to perform urethroplasty and penile elongation before bladder neck reconstruction. A small, incontinent bladder with reflux is hardly an ideal situation for bladder neck reconstruction and ureteral reimplantation. Before bladder neck reconstruction there was an average increase in bladder capacity of 95 mL within 18 months after epispadias repair in the patients with an initial small bladder capacity and a continence rate of 87% after the continence procedure (Peters et al., 1988). In a series by Ben-Chaim et al. (1995b) composed exclusively of patients with complete male epispadias, bladder capacity increased by an average of 42 mL within 18 months after urethroplasty. Nine (82%) of 11 patients were dry day and night after an average of 9 months.

In epispadias, as in bladder exstrophy, bladder capacity is the predominant indicator of eventual continence (Ritchey et al., 1988). Arap et al. (1988) **reported higher continence rates in patients who had an adequate bladder capacity before bladder neck reconstruction than in those with inadequate capacity (71% vs. 20%, respectively).** In addition, in Arap's group of patients with complete epispadias, most obtained continence within 2 years, similar to results in patients with CBE.

A firm intrasymphyseal band typically bridges the divergent symphysis, and an osteotomy is not usually performed. The Young-Dees-Leadbetter bladder neck plasty, Marshall-Marchetti-Krantz suspension, and ureteral reimplantation are performed when the bladder capacity reaches approximately 100 mL, which usually occurs between 4 and 5 years of age when the child is ready to be dry. Genital reconstruction procedures in epispadias and exstrophy are similar. The following reconstructive maneuvers must take place: release of dorsal chordee and division of the suspensory ligaments; dissection of the corpora from their attachments to the inferior pubic ramus; lengthening of the urethral groove; and lengthening of the corpora, if needed, by incision and anastomosis or grafting or by medial rotation of the ventral corpora in a more downward direction.

Urethral reconstruction in complete epispadias has been performed in many ways. A transverse island flap was used by Monfort et al. (1987). The urethra, once reconstructed, can be positioned between and below the corpora (Cantwell, 1895; Gearhart et al., 1992, 1995c; Ransley et al., 1989). Mitchell and Bägli (1996) reported their experience with a complete penile disassembly technique, and a multicenter experience was reported in a total of 17 patients from four institutions (Zaontz et al., 1998). Chordee was reliably corrected, erectile function was preserved, the urethra was eventually situated in a cosmetic fashion, and satisfactory cosmesis was achieved. Caione and Capozza (2001) reported on their experience with the use of penile disassembly and reapproximation of the perineal muscle complex for the management of boys with epispadias, indicating the ability to achieve continence without the need for additional bladder neck reconstruction. A recent small series by Kibar et al. (2009b) of patients with complete epispadias showed that complications with use of the disassembly repair were in the acceptable range. Unlike the use of this in the exstrophy group, there was no ischemia of the glans or corpora. However, most patients required additional surgery because hypospadias was created in a number of patients. Repair of this hypospadias can be challenging and can have high complication rates (Berrettini et al., 2011). Cervellione et al. (2010) did report on 4 patients who underwent penile disassembly or radical soft-tissue mobilization (Kelly procedure) who had significant corporeal loss after surgery. Ransley and Surer et al. reported excellent results using the modified Cantwell-Ransley procedure, saving cavernocavernostomy for patients with very severe chordee and especially those in the older age group (Kajbafzadeh et al., 1995; Surer et al., 2000). For detailed description of the surgical reconstruction, see the previous discussion in the section on bladder exstrophy.

It was formerly thought that the effect of urethral lengthening and prostatic enlargement may be significant in complete epispadias by increasing outlet resistance if continence was not perfect as the child became older. Earlier in a series by Arap et al. (1988), the establishment of continence had no relation to puberty and usually occurred within 2 years, usually preceding puberty by several years. In the series reported by Ben-Chaim et al. (1995b), as stated previously, all patients obtained daytime continence at a mean of 9 months after bladder neck reconstruction, and 9 (82%) of 11 patients attained total day and night continence. All patients voided spontaneously. After a mean follow-up of 7 years, all patients maintained normal upper tracts and kidney function. All of them had cosmetically pleasing genitalia, as judged by parents, patients, and physicians, and experienced normal erections. A 36-year-old patient was married and had fathered three children. Many of the patients were younger than 16 years and had not yet become sexually active. Results of urethroplasty in epispadias have been reported in a number of publications (Kajbafzadeh et al., 1995; Mesrobian et al., 1986; Ransley et al., 1989; Zaontz et al., 1998). In a modern series of modified Cantwell-Ransley repairs reported by Surer et al. (2000), the incidence of postoperative fistula in the 3-month period after surgery was 19%, and the incidence of urethral stricture formation was less than 10%. Catheterization and cystoscopy could easily negotiate the neourethral channel in all patients who underwent a modified Cantwell-Ransley epispadias repair. In another modern series reported by Mollard et al. (1998), the continence rate was 84% and the fistula rate was less than 10%. In Mollard's series with long-term follow-up, patients had normal erections; the vast majority had regular sexual intercourse, and most had normal ejaculation or had fathered children. Most of Surer's patients were young, and assessment of genital reconstruction must be deferred until these patients are sexually mature and active (Surer et al., 2000). Hafez and Helmy (2011) reported on three patients with isolated penopubic epispadias who underwent postpubertal reconstruction using penile disassembly, indicating good cosmesis with a meatus at the tip.

Although many methods of epispadias repair exist, meticulous follow-up of the urethra, appropriate selection of patients, and surgical experience remain the milestones of success. Last, Ransley et al. (Kajbafzadeh et al., 1995) obtained very good results using a modified Cantwell-Ransley repair in a large number of patients with epispadias. The fistula rate was 4%, and the urethral stricture rate was 5.3%. Baird et al. (2005b) reported on 129 boys who underwent a modified

Cantwell-Ransley repair. Of this group, 32 had penopubic epispadias. Twenty-four procedures were primary repairs and eight were secondary repairs. Urethrocutaneous fistula occurred in 13% of primary and 25% of secondary repairs. A urethral stricture occurred in one patient.

Achievement of urinary continence in patients with isolated epispadias is summarized in Table 31.5. A majority of these patients underwent reconstruction by means of a modified Young-Dees-Leadbetter bladder neck plasty. Urinary continence was obtained in 82% of male patients (Ben-Chaim et al., 1995b). As in the exstrophy population, repair of the epispadiac deformity results in an increase of outlet resistance and possible increase in bladder capacity before bladder neck reconstruction. Although complete epispadias and bladder exstrophy patients achieve improvement in bladder capacity after epispadias repair, the mean increase in overall capacity is higher in those with complete epispadias. This increase in bladder capacity may account for increased continence in this group compared with the CBE population. Clinically, these bladders are more supple, easier to mobilize, and more amenable to bladder neck reconstruction. Ben-Chaim et al. (1995b) reported that the mean time to initial continence after bladder neck reconstruction was 90 days in patients with complete male epispadias compared with 110 days in those with bladder exstrophy. These results suggest that for patients with complete epispadias, bladder capacity before reconstruction and the rate of achieving continence afterward are better than in exstrophy. The reason may be that the bladder is not exposed in utero and does not have any scarring from prior closure; therefore its potential for expansion is higher.

In a different approach to the treatment of incontinence associated with epispadias reported by Duffy and Ransley (1998), 12 boys aged 3 to 7 years underwent endoscopic submucosal injection of plastic microspheres. All patients had undergone a modified Cantwell-Ransley epispadias repair before injection. The procedure was performed 24 times, with a total volume of 83 mL of material injected into 59 sites in the posterior urethra. Mean follow-up was 10.8 months. Three patients (25%) were rendered completely dry, the degree of incontinence was improved in 6 patients, and there was no change in 3 patients. The authors offered this approach as an alternative to bladder neck reconstruction in patients with primary epispadias. Ben-Chaim et al. (1995a) reported that submucosal injection of collagen in the bladder neck area can have a role in improving stress incontinence when the patient with complete epispadias has incomplete urinary control or as an adjunct after bladder neck reconstruction. In a recent study by Kibar et al. (2009a) of complete epispadias, 1 patient out of 12 was continent after bladder neck injection.

Kramer et al. (1986) reported the success of genital reconstruction in epispadias, with good long-term follow-up ending with a straight penis angled downward in almost 70% of patients, with normal erectile function. Of this group, 80% had satisfactory sexual intercourse, and of 29 married patients, 19 had fathered children. These results were mirrored in the long-term follow-up study of Mollard et al. (1998).

A carefully constructed and well-planned approach to the management of urinary incontinence in genital deformities associated with complete epispadias should provide a satisfactory cosmetic appearance, normal genital function, and preservation of fertility potential in most patients.

Female Epispadias

Female epispadias is a rare congenital anomaly; it occurs in 1 of every 484,000 female patients (Gearhart and Jeffs, 1998; Fig. 31.30). **We use the classification of Davis** (1928), **which describes three degrees of epispadias in female patients** (Figs. 31.31A to D). **In the least severe degree of epispadias, the urethral orifice simply appears patulous. In intermediate epispadias, the urethra is dorsally split along most of the urethra. In the most severe degree of epispadias, the urethral cleft involves the entire length of the urethra and sphincteric mechanism and the patient is rendered incontinent** (Fig. 31.31). The genital defect is characterized by a bifid clitoris. The mons is depressed in shape and coated by a smooth, glabrous area of skin. Beneath this area, there may be a moderate amount of subcutaneous tissue and fat, or the skin may be closely applied to the anterior and inferior surface of the symphysis pubis. The labia minora are usually poorly developed and terminate anteriorly at the corresponding half of the bifid clitoris, where there may be a rudiment of a preputial fold. These external appearances are most characteristic: on minimal separation of the labia, one sees the urethra, which may vary considerably, as mentioned previously. The symphysis pubis is usually closed but may be represented by a narrow fibrous band. The vagina and internal genitalia are usually normal. Because the external appearance changes may be minimal, some children are identified only because of persistent incontinence (Shetty et al., 2011; Yeni et al., 2004).

Sphincter is usually involved. *SYM,* Symphysis. (Used with permission of Brady Urological Institute.)

Associated Anomalies

The ureterovesical junction is inherently deficient in patients with epispadias, and the ureters are often laterally placed in the bladder with a straight course so that reflux occurs. The incidence of reflux is reported to be 30% to 75% (Gearhart et al., 1993a; Kramer and Kelalis, 1982b). Because there is no outlet resistance, the bladder is small and the wall is thin. After initial reconstruction, the urethral resistance that is created allows the bladder to grow and develop to an acceptable capacity for bladder neck reconstruction.

Surgical Objectives

Objectives for repair of female epispadias parallel those devised for male patients: (1) achievement of urinary continence, (2) preservation of the upper urinary tracts, and (3) reconstruction of functional and cosmetically acceptable external genitalia.

Operative Techniques

With the patient in the lithotomy position, the defect of the female epispadias with incontinence is apparent (Fig. 31.32A). The two halves of the clitoris are widely separated, and the roof of the urethra is cleft between the 9 o'clock and 3 o'clock positions. The smooth mucosa of the urethra tends to blend cephalad with the thin, hairless skin over the mons. The urethral incision is begun at the cephalad extent of the vertical incision at the base of the mons and is brought inferiorly through the full thickness of the urethral wall at the 9 o'clock and 3 o'clock positions (Fig. 31.32B). Sutures can be placed in the urethra to permit downward traction on the urethra so that the roof of the urethra is excised to a level near the bladder neck (Fig. 31.32C). Often one finds the dissection proceeding under the symphysis. An inverting closure of the urethra is then performed over a 10-Fr Foley catheter. Suturing is begun near the bladder neck and progresses distally until closure of the neourethra is accomplished (Fig. 31.32D). Attention is then given to denuding the medial half of the bifid clitoris and the labia minora so that proper genital coaptation can be obtained.

(J) Creation of clitoral hood. (K) Completion of mons closure. (Copyright Brady Urological Institute.)

After this is done, fat from the mons and subcutaneous tissue can be used to cover the suture line and obliterate the space in front of the pubic symphysis (Figs. 31.32E and F). The two halves of the clitoris and labia minora are brought together using interrupted sutures of 6-0 polyglycolic acid. The corpora may be partially detached from the anterior ramus of the pubis to aid in the urethral closure. Also, bringing these tissues together may contribute by adding resistance to the urethra. Mons closure is further aided by mobilizing subcutaneous tissue laterally and bringing it medially to fill any prior depression that remains (Fig. 31.32G). The subcutaneous layer is closed with 4-0 polyglactin suture in an interrupted fashion (Fig. 31.32H). The skin is closed with interrupted sutures of 6-0 polypropylene (Figs. 31.32I to K).

A 10-Fr catheter is left indwelling for 5 to 7 days. Should the patient undergo simultaneous bladder neck reconstruction, a Foley catheter is not left in the urethra and the patient is placed in the supine position for the abdominal part of the procedure.

Achievement of a satisfactory cosmetic appearance of the external genitalia and urinary continence in the female child with epispadias represents a surgical challenge. Many operations have been reported to control continence in the epispadias group, but the results are disappointing. These procedures include transvaginal plication of the urethra and bladder neck, muscle transplantations, urethra twisting, cauterization of the urethra, bladder flap, and Marshall-Marchetti vesicourethral suspension (Davis, 1928; Gross and Kresson, 1952; Marshall et al., 1949; Stiles, 1911). These procedures may increase urethral resistance, but they do not correct incontinence or the malformed anatomy of the urethra, bladder neck, and genitalia.

The challenge of the small bladder in the female epispadias patient is comparable with a situation seen in patients with a closed exstrophy. The small, incontinent bladder, with or without reflux, is hardly an ideal setting for a successful bladder neck reconstruction and ureteral reimplantation. A third of all incontinent epispadias patients have a bladder capacity of less than 60 mL, in our experience and that of Kramer and Kelalis (1982b). Bladder augmentation, injection of polytetrafluoroethylene (Teflon) in the bladder neck area, and simultaneous bladder neck reconstruction and bladder neck augmentation have been offered as a solution to this challenge. However, primary closure of the epispadiac urethra in children with closed exstrophy was found to increase bladder capacity without causing hydronephrosis, and this approach has been applied to male and female patients with epispadias (Ben-Chaim et al., 1995b;

Gearhart and Jeffs, 1989a; Peters et al., 1988). Although we typically perform urethral and genital reconstruction at 6 months to 1 year of age, we advocate delaying bladder neck reconstruction until the child is 4 to 5 years old. Not only does this delay allow the bladder to increase in capacity but also it allows the child to accept essential instructions for toilet training, which is critical to achieving satisfactory continence in the postoperative state.

Data from de Jong et al. (2000) combined a standard exterior genitoplasty plus urethroplasty with a percutaneous bladder neck suspension. The authors felt the suspension moved the bladder neck into an intra-abdominal position. In this small series, one patient was dry and voiding, two required bladder neck bulking agents, and one was on CIC. In another small series from India, Bhat et al. (2008) performed a urethroplasty and the perineal musculature was double-breasted over the urethral closure from the bladder neck distally. Bhat et al. reported impressive results with two totally continent, one partially continent, and one continent patient after bladder neck reconstruction.

Surgical Results

The continence rate of 87.5% in our female patients is comparable with that of Hanna and Williams (1972), who found a 67% continence rate in female patients with good bladder capacity, and those of Kramer and Kelalis (1982b), who reported an 83% continence rate in patients with adequate bladder capacity. All of our patients seen for primary treatment have achieved a capacity in excess of 80 mL (see Table 31.5).

Hendren (1981) and Kramer and Kelalis (1982b) showed that genitourethral reconstruction can be accomplished with satisfactory results. At our institution, patients who underwent prior urethral and genital reconstruction had a mean bladder capacity at bladder neck reconstruction of 121 mL, making the bladder suitable for the reconstruction and eventual continence without the use of augmentation cystoplasty or need for intermittent catheterization.

The time interval to achieve continence in our patients was a mean of 18 months for those who underwent genitourethral and bladder neck reconstruction in one procedure and 23 months for those who underwent preliminary urethroplasty and genital reconstruction after bladder neck reconstruction. In a series by Klauber and Williams (1974), the mean interval to acceptable continence was 2.25 years. Also, in a series by Kramer and Kelalis (1982b), some patients became continent within a short period, whereas complete continence was delayed for several years in others. The time delay for achieving continence may represent increased pelvic muscular development, as suggested by Kramer and Kelalis (1982b). In regard to the interval to continence, no advantage appears to be gained by preliminary urethroplasty. However, we believe that the advantage gained by increased bladder capacity at the time of bladder neck reconstruction outweighs any advantage gained by a combined approach. Suson et al. (2013) compared 22 girls with complete female epispadias with 23 girls with CBE. Although girls with female epispadias had reconstruction at a later age than those with CBE, bladder growth rate did not differ between the two groups (Suson et al., 2013). Neither group had any difference in number of surgical procedures, development of continence with or without the need for bladder neck reconstruction, or eventual need for continent urinary diversion.

Key Points: Male and Female Epispadias: Priorities in Management

- Degree of epispadias and continence
- Associated anomalies
- Bladder capacity
- Aesthetic and functional genitalia

Cloacal Exstrophy

Cloacal exstrophy includes a spectrum of abnormalities but is primarily an anterior abdominal wall defect. A reported incidence of 1 : 200,000 to 1 : 400,000 makes this one of the rarer urologic abnormalities (Hurwitz et al., 1987). Although prior reports have suggested a male-to-female ratio of 2 : 1 (Gearhart and Jeffs, 1998), a large study by Boyadjiev et al. (2004a) indicated that the sex ratio may be 1 : 1. Most cases are sporadic, and isolated incidences of unbalanced translocations have been reported to be potentially causative (Thauvin-Robinet et al., 2004); however, one report noted recurrence in siblings, perhaps indicating a more multifactorial cause. Recent reports have indicated a greater incidence of cloacal exstrophy associated with maternal exposure to cigarette smoke (Gambhir et al., 2008). Mothers of infants with cloacal exstrophy were more compliant with preconceptional folate use. Associated defects of the neurospinal axis, intestinal tract, and urogenital and skeletal systems are frequently noted. When neurospinal defects and omphalocele coexist with cloacal exstrophy, the term *OEIS complex* (omphalocele, exstrophy, imperforate anus, spinal defects) has been used (Keppler-Noreiul, 2001). Advances in the care of critically ill children has resulted in most infants with cloacal exstrophy surviving into adulthood. The focus of management has therefore shifted to improving QoL (Mathews et al., 1998).

Anatomic Considerations

The classic constellation of anomalies that are noted in children with cloacal exstrophy includes exstrophy of the bladder, complete phallic separation, wide pubic diastasis, exstrophy of the terminal ileum between the two halves of the bladder, a rudimentary hindgut, imperforate anus, and the presence of an omphalocele. Many children have associated spinal defects, and various lower extremity malformations may be noted (Jain and Weaver, 2004; Loder and Dayioglu, 1990). The urogenital anomalies in cloacal exstrophy are similar to those seen with CBE (see previous), although they are typically of greater severity.

Neurospinal Abnormalities

Abnormalities of the spinal cord or vertebral column or both have been noted in 85% to 100% of children with cloacal exstrophy (Appignani et al., 1994; McLaughlin et al., 1995). Although most patients have lumbar myelodysplasia (80%), thoracic defects may be noted in 10%, with the remaining having sacral defects. In a large series of 34 patients from a single center with cloacal exstrophy and associated spinal defects, Mathews et al. (1998) noted lipomeningocele in 17, myelomeningocele in 8, and spina bifida and isolated cord tethering in 7 and 2 patients, respectively. The nearly universal incidence of spinal abnormalities has led some authors to suggest MRI for all patients with a diagnosis of cloacal exstrophy (Cohen, 1991). Spinal ultrasound evaluation, which is easily performed, has been noted to be comparable with MRI for the diagnosis of spinal anomalies in infants with cloacal exstrophy (Dick et al., 2001). Karrer et al. (1988) noted that only 1 in 5 children with spinal dysraphism noted on ultrasonography had a sacral abnormality visible on the skin surface.

The embryologic basis for the neurospinal defects associated with cloacal exstrophy has been postulated to be secondary to disruption of the tissue of the dorsal mesenchyme rather than failure of neural tube closure (McLaughlin et al., 1995). Alternatively, it has been suggested that the defects that lead to the formation of cloacal exstrophy may lead to the developing spinal cord and vertebrae being pulled apart (Cohen, 1991). Functional deficits can range from patients who have almost normal sensation of the pelvis and lower extremity to patients who are wheelchair bound. The presence of a clinically significant neurologic anomaly was found to negatively affect the development of continence (Husmann et al., 1999). Only 1 of 13 neurologically impaired patients in this series developed voided continence.

The neuroanatomic dissections performed by Schlegel and Gearhart (1989) further indicate that the neuroanatomic landmarks in the infant with cloacal exstrophy are different from those in the normal newborn, with the autonomic bladder innervation being derived from a more medial location (Fig. 31.33). This potentially puts the nerve supply in jeopardy during initial bladder dissection and reconstruction and can potentially leave the bladder neuropathic after reconstruction (Husmann et al., 1999). Innervation to the duplicated corporeal bodies arises from the sacral plexus, travels in the midline, perforates the pelvic floor, and courses medially to the hemibladders (Schlegel and Gearhart, 1989). Innervation abnormalities were also noted at a histologic level in the studies by Rosch et al. (1997). When compared with those in patients with bladder exstrophy, the neural elements identified on immunohistochemical evaluation were found to show significant structural abnormalities.

Skeletal System Abnormalities

Anomalies of the skeletal system are universally noted in children with cloacal exstrophy. The pubic diastasis noted in the exstrophy-epispadias complex are seen at their most extreme with cloacal exstrophy. Sponseller et al. (1995), studying patients with the exstrophy complex, noted that the posterior segment of the pelvis in children with cloacal exstrophy was angled farther posteriorly and there was a greater likelihood of asymmetry between the two sides. Similarly, the anterior segment of the pelvis had more severe degrees of external rotation. The actual length of the bone segments, however, was similar between those with cloacal and classic exstrophy. The interpubic distance (diastasis) in children with cloacal exstrophy was noted to be almost twice that in children with CBE. Malformation of the sacroiliac joints and side-to-side asymmetry were also noted. Most children with cloacal exstrophy therefore require osteotomy for successful reconstruction. **Stec et al.** (2003) **noted that microscopically the bones in children with cloacal exstrophy were similar to those in normal controls and were developing at a similar rate, indicating that the potential for growth was also similar.**

Vertebral anomalies not associated with myelodysplasia were noted in 8 of 37 children with cloacal exstrophy (Mathews et al., 1998). Loder and Dayioglu (1990) noted vertebral anomalies in 3 of 5 children with cloacal exstrophy. Absence or shortening of limbs was also noted, as were clubfoot malformations. Skeletal and limb anomalies were also reported by Diamond (1990) in 12% to 65% of patients. The vast majority were clubfoot deformities, although absence of feet, severe tibial or fibular deformities, and congenital hip dislocations were commonly noted in this group of patients. A similar high incidence of foot abnormalities and greater than normal abduction of the hips was noted in a study by Greene et al. (1991).

Intestinal Tract Abnormalities

Gastrointestinal tract anomalies occur in virtually all patients with cloacal exstrophy. In Diamond's series (1990), the incidence of omphalocele was 88%, and most other series report an incidence of 95% or greater. In the series reported by Mathews et al. (1998), 100% of patients had an omphalocele. Omphaloceles vary in size and usually contain small bowel or liver or both. Immediate closure of the omphalocele defect in the newborn period is advised to prevent subsequent rupture.

Hurwitz et al. (1987), in a large review of cloacal exstrophy patients, reported a 46% incidence of associated gastrointestinal tract anomalies, with malrotation, duplication anomalies, and anatomically short bowel occurring with equal frequency. A hindgut remnant of varying size is also noted in most patients. Hurwitz noted a 23% incidence of short gut syndrome, which is compatible with the 25% incidence reported by Diamond (Diamond, 1990; Hurwitz et al., 1987).

It now seems well accepted that short gut syndrome may occur in the presence of normal small bowel length, suggesting absorptive dysfunction and emphasizing the absolute need to preserve as much large bowel as possible. If not used for incorporation into the fecal stream, the hindgut remnant may be preserved for use in urogenital tract reconstruction (Mathews et al., 1998). Modern techniques have reduced the incidence of short gut syndrome in the majority of patients (Sawaya et al., 2010).

Genitourinary Abnormalities

Müllerian anomalies have been frequently noted in conjunction with cloacal exstrophy. The most commonly reported müllerian anomaly was uterine duplication, seen in 95% of patients (Diamond, 1990). The vast majority of these patients had partial uterine duplication, predominantly a bicornate uterus. Vaginal duplication occurred in 65% of patients, and vaginal agenesis was seen in 25% to 50% of patients. In a report by Hurwitz et al. (1987), cases of complete duplication of the uterus and fallopian tubes associated with both vaginal duplication and vaginal agenesis were noted. Gearhart and Jeffs (1991b) recommended preservation of all müllerian duplication anomalies for possible use in reconstructing the lower urinary tract.

Upper urinary tract anomalies occurred in 41% to 60% of patients in Diamond's review (1990). The most common anomalies were pelvic kidney and renal agenesis, both occurring in up to one-third of patients. Hydronephrosis and hydroureter were common, occurring in one-third of patients. Multicystic dysplastic kidneys and fusion anomalies were seen less frequently. Ectopic ureters draining to the vasa in the male and into the uterus, vagina, or fallopian tubes in the female were also reported (Diamond, 1990). A similar incidence of upper tract defects was noted by Mathews et al. (1998). Ureteral duplication, congenital stricture, and megaureter were also reported.

Genital anomalies in the male have typically included complete separation of the two phallic halves and accompanying separation of the scrotal halves. Asymmetry of these structures can also be seen and can provide additional challenges to successful reconstruction. Testes may be noted in the scrotum but are frequently noted to be undescended, and associated inguinal hernias are a common finding. Girls typically have widely divergent clitoral halves.

The lower urinary tract is typically composed of two exstrophied hemibladders flanking the exstrophied intestinal segment. Each bladder half usually drains the ipsilateral ureter and is closely related to the ipsilateral phallic segment. Variations of anatomy, however, are frequently seen, and every patient has unique anatomic features.

Additional System Anomalies

Life-threatening cardiovascular and pulmonary anomalies are rarely seen in cloacal exstrophy. Reported cases included two patients with cyanotic heart disease and one with aortic duplication. A bilobed lung was reported in two patients and an atretic right upper lung in one. Also, Schlegel and Gearhart (1989) reported caval duplication in their anatomic dissection of a patient with cloacal exstrophy.

Because of the complexity and the multisystem nature of cloacal exstrophy, Manzoni et al. (1987) have devised a grid for the clarification of anatomy in each patient and to permit planning for reconstruction (Fig. 31.34). This permits the standard form of cloacal exstrophy to be separated from variants and allows the soft-tissue components of the defect to be described systematically.

FIG. 31.34 Coding grid used to describe cloacal exstrophy and its variants. *$B1_E$,* Everted bowel; *HBL_E,* hemibladder; *HG,* hindgut; *HP,* hemiphallus; *O,* omphalocele. (From Manzoni GA, Ransley PG, Hurwitz RS: Cloacal exstrophy and cloacal exstrophy variants: a proposed system of classification, *J Urol* 138:1065. 1987.)

Cloacal Exstrophy Variants

Cloacal exstrophy usually includes an open and everted intestinal segment situated between two hemibladders, an omphalocele, and a blind-ending tailgut with an imperforate anus. The pubic symphysis and the rectus muscles are widely separated. The phallus is bifid, and the scrotum or labia are split and laterally displaced. In girls the vagina is bifid with two uteri. Given that cloacal exstrophy encompasses abnormalities of the genitourinary, gastrointestinal, and musculoskeletal systems, and often the neurologic system, it is not surprising that a wide range of variants from the classic presentation have been reported. The treatment of cloacal exstrophy has evolved from palliation of an almost universally fatal disorder into complex genitourinary and gastrointestinal reconstruction and a near-normal life span.

Of six cases reported by Lowentritt et al. (2005) with cloacal variants, five were skin covered and one involved duplication of the bowel and hemibladders. Cases of cloacal exstrophy are challenging in their surgical management, and the variations of the complex add to the difficulties of initial diagnosis and management. Only by using a combination of genitograms, retrograde ureterograms, and bowel continence studies was it possible to understand the complex anatomy of the patients in these groups. Three patients had no spinal abnormalities and one had spina bifida occulta. Three patients in this group had innervation of the pelvic floor, enabling successful Pena procedures in two, with the third patient awaiting the procedure. Cloacal variants have a lower incidence of spinal abnormalities and a higher rate of fecal continence compared with their classic presentations. Overall, these patients had a low incidence of severe comorbid conditions. Therefore appropriate treatment of these genitourinary malformations can significantly affect and improve QoL.

Prenatal Diagnosis

Since the initial description of cloacal exstrophy in the early 1980s, further refinements in its prenatal ultrasound diagnosis have occurred (Meizner and Bar-Ziv, 1985). These authors indicated that the three main criteria used to identify the diagnosis were a large midline infraumbilical anterior abdominal wall defect, lumbosacral myelomeningocele, and failure to visualize the urinary bladder. Chitrit et al. (1993) reported the diagnosis of monozygotic twins with cloacal exstrophy detected during antenatal ultrasound screening. Since these initial reports, there have been only occasional case reports of prenatal diagnosis of cloacal exstrophy, and only 15% of patients with this anomaly have been diagnosed by prenatal ultrasonography, according to the literature. With the marked improvements in survival of patients with cloacal exstrophy in the last

20 years and the common application of fetal ultrasonography, early diagnosis may permit appropriate prenatal counseling for parents and expedite postnatal care.

Austin et al. (1998) reviewed 20 patients with this abnormality, expanded on the diagnostic findings, and proposed major and minor criteria for the prenatal ultrasound diagnosis of cloacal exstrophy, based on the frequency of occurrence rather than the severity of individual findings. A criterion was considered major if it was present in more than 50% of cases. The gestational age at diagnosis of cloacal exstrophy ranged from 15 to 32 weeks (mean, 22 weeks). Major diagnostic criteria included nonvisualization of the bladder in 91%, a large midline infraumbilical anterior wall defect or a cystic anterior wall structure in 82%, an omphalocele in 77%, and a myelomeningocele in 68%. Minor criteria included lower extremity defects in 23%, renal anomalies in 23%, ascites in 41%, widened pubic arches in 18%, narrow thorax in 9%, hydrocephalus in 9%, and a single umbilical artery in 9%. Hamada et al. (1999) reported a single case in which ultrasonography revealed a wavy cordlike segment of soft tissue protruding from the anterior abdominal wall of the fetus below the umbilicus. This was found to be prolapsed terminal ileum, which resembled the trunk of an elephant. The authors suggested that this sonographic image be added to the criteria described by Austin et al. (1998) for making a prenatal diagnosis of cloacal exstrophy.

MRI has been used successfully for the prenatal evaluation of cloacal exstrophy (Chen et al., 2008). In conjunction with ultrasonography, excellent definition of anatomy can now be obtained. MRI was found to be superior to ultrasonography when a normal bladder is not identified (Calvo-Garcia et al., 2013). In addition, MRI was able to definitively identify the omphalocele, gender ambiguity, and spinal defect that were not easily defined with ultrasonography (Goto et al., 2012).

Antenatal diagnosis now permits parental counseling and postnatal management. Extensive parental counseling regarding the significant anatomic anomalies that constitute the complex is appropriate in conjunction with psychological support. Prenatal identification of cloacal exstrophy should permit planned maternal-fetal transfer to a center with subspecialty experience for perinatal management (Keppler-Noreuil et al., 2007).

Surgical Reconstruction of Cloacal Exstrophy

The initial successful reconstruction of cloacal exstrophy was reported by Rickham and Johnston (Rickham, 1960). Survival in the 1970s remained at about 50%; however, the institution of intensive postnatal care led to improvement in survival in the 1980s to almost 100%. Where access to subspecialty care is limited, survival can be severely compromised.

Evaluation and Management at Birth

Immediate management is directed to the medical stabilization of the infant. Complete physical examination and determination of the various anatomic defects present allow creation of short- and long-term management strategies (Box 31.1). This initial planning stage should include decisions about gender assignment. The bowel and bladder segments are kept moist with protective plastic dressings as with bladder exstrophy (Gearhart and Jeffs, 1998). Presence of neurospinal abnormalities requires immediate neurosurgical evaluation. Consultations from social work, pediatric orthopedic surgery, and other disciplines should be obtained. Evaluation of the genitalia and gender assignment should be made by a gender assignment team, including a pediatric urologist, pediatric surgeon, pediatrician, pediatric endocrinologist, and child psychologist or psychiatrist. Gender assignment decisions should be made in conjunction with appropriate parental counseling and involvement. In a large medical center with experience in dealing with complex malformations, these multiple consultations should be done in a short period of time. If there are medical concerns or the bladder segments are too small for closure, delayed closure after initial intestinal diversion is appropriate (Mathews et al., 1998).

Box 31.1

Modern Functional Reconstruction of Cloacal Exstrophy

Immediate Neonatal Assessment

Evaluate associated anomalies
Decide whether to proceed with reparative surgery

Functional Bladder Closure (Soon After Neonatal Assessment)

One-Stage Repair (Few Associated Anomalies)

Excision of omphalocele
Separation of cecal plate from bladder halves
Joining and closure of bladder halves and urethroplasty
Bilateral anterior innominate and vertical iliac osteotomy
Terminal ileostomy/colostomy
Genital revision if needed

Two-Stage Repair

- First stage (newborn period)
  - Excision of omphalocele
  - Separation of cecal plate from bladder halves
  - Joining of bladder halves
  - Gonadectomy in male with unreconstructible phallus
  - Terminal ileostomy/colostomy
- Second stage
  - Closure of joined bladder halves and urethroplasty
  - Bilateral anterior innominate and vertical iliac osteotomy
  - Genital revision if needed

Anti-incontinence/Reflux Procedure (Age 5–7 yr)

- Bladder capacity ≥100 mL (very small select group of patients)
  - Young-Dees-Leadbetter bladder neck reconstruction
  - Bilateral Cohen ureteral reimplantations
  - Bowel and/or stomach segment used to augment bladder
  - Continent diversion with abdominal/perineal stoma

Vaginal Reconstruction

Vagina constructed or augmented using colon, ileum, or full-thickness skin graft

Key Points: Evaluation of the Newborn With Cloacal Exstrophy

- Neurospinal anomalies
- Size of the omphalocele
- Size and quality of the bladder templates
- Width of pubic diastasis
- Other associated anomalies

Gender Assignment

Because of the significant separation of the corpora of the penis and scrotum and the reduction in corporeal size noted in boys with cloacal exstrophy, early reports recommended universal gender reassignment of boys (46,XY) with cloacal exstrophy to functional females (Tank and Lindenaur, 1970). To this end, bilateral orchiectomy was combined with phallic reconstruction as a functional clitoris and early or delayed vaginoplasty. Reiner and Gearhart (2004) have reported on 29 males with cloacal exstrophy who had gender reassignment to female. Psychosexual evaluation indicated that all of these patients had a marked male shift in psychosexual development despite having no pubertal hormonal surges. Mirheydar et al. (2009) reported a case of masculinization in a 46,XY gender-converted patient secondary to an ectopic testis. A comparison of patients with cloacal exstrophy and other cloacal anomalies at the Great Ormond Street Hospital for Sick Children, however, indicated no difference in social or behavioral competence or psychological problems. Gender assignment was not associated with childhood psychological, emotional, or behavioral problems (Baker Towell and Towell, 2003). Schober et al. (2002), reporting on 14 children who had undergone early gender reassignment, indicated that although patients had masculine childhood behavior, they had a feminine gender identity. Currently, however, most authors recommend assigning gender that is consistent with karyotypic makeup of the individual if at all possible (Fig. 31.35). A recent survey of pediatric urologists indicated that two-thirds of respondents favored gender-congruent assignment (Diamond et al., 2006). This policy can be supported by a report indicating that the histology of the testis at birth is normal (Mathews et al., 1999a). Furthermore, with evolution of techniques for phallic reconstruction, a functional and cosmetically acceptable phallus can now be constructed (Husmann et al., 1989b; Massanyi et al., 2012).

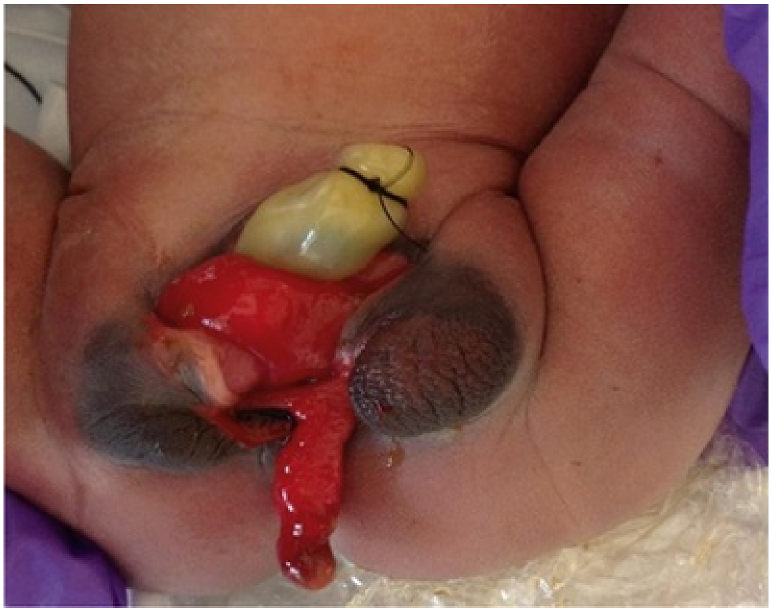

FIG. 31.35 A 46,XY child with cloacal exstrophy with a dominant right hemiphallus. This child was reconstructed and reared as male.

Immediate Surgical Reconstruction

Cloacal exstrophy patients should undergo carefully planned and individualized reconstructions (Lund and Hendren, 1993; Mathews et al., 1998; Ricketts et al., 1991). For infants with spinal dysraphism and myelocystocele, neurosurgical consultation should be obtained and closure undertaken as soon as the infant's condition is medically stable. After closure of the myelocystocele, long-term follow-up is mandatory to evaluate for subtle changes in the neurologic evaluation that could herald cord tethering. Symptomatic spinal cord tethering can be seen in up to 33% of children (McLaughlin et al., 1995). A more recent series evaluating neuro-orthopedic manifestations in cloacal exstrophy indicated that 57 of 68 children had spina bifida (Suson et al., 2010). Of 62 children who were of walking age, 37 were able to ambulate completely, 17 ambulated with devices, and 8 were wheelchair bound.

Neonatal omphalocele closure is recommended to prevent untimely rupture and is typically combined with intestinal diversion. Formerly, initial attempts focused on ileostomy with resection of the hindgut remnant. Since the recognition of the metabolic changes that occur in patients with ileostomy, an attempt is always made to use the hindgut remnant to provide additional length of bowel for fluid absorption (Husmann et al., 1989a; Mathews et al., 1998). Tubularization of the cecal plate with end colostomy has been shown to be beneficial in reducing the incidence of short gut syndrome (Sawaya et al., 2010). Enlargement of the hindgut remnant and increased water absorption have been noted in children who have had the hindgut remnant incorporated into construction of a fecal colostomy (Taghizadeh et al., 2009). The hindgut segment may be anastomosed in an isoperistaltic or retroperistaltic fashion to increase motility and generate formed stool. Children who have anal stenosis and not imperforate anus may have the capability for later continence and may be treated with a pull-through procedure (Ricketts et al., 1991). If the hindgut remnant is not used for bowel reconstruction, it should be left as a mucous fistula to be used for later bladder augmentation or vaginal reconstruction (Lund and Hendren, 1993; Mathews et al., 1998). If gastrointestinal reconstruction is combined with bladder closure, approximation of the pubis, usually with osteotomies, is beneficial in reconstruction of the pelvic ring and increases the potential for successful bladder and abdominal wall closure (Mathews et al., 1998). Some authors have suggested that gastrointestinal reconstruction after initial fecal diversion be delayed for 1 to 2 years of observation (Soffer et al., 2000). After this time, radiographic evaluation is performed to determine residual colonic length. If near-normal colonic length is noted, a pull-through procedure is performed. If there is short colon but the patient is able to make solid stool, the patient may still be a candidate for pull-through procedures. A number of patients who can make solid stool can now be managed with pull-through procedures in conjunction with bowel management strategies to help them stay clean (Levitt et al., 2008). Bowel-lengthening procedures have also been used to improve absorptive function and benefit nutritional outcomes (Figueroa-Colon et al., 1996). Children who are unable to make solid stool are typically managed with a permanent fecal stoma.

At the initial stage of omphalocele closure, if it is determined that bladder and abdominal wall closure may not be accomplished, the bladder halves are approximated in the midline without further dissection and the defect is converted to a bladder exstrophy (Mathews et al., 1998; Ricketts et al., 1991). This permits abdominal distention to allow enlargement of this bladder plate for later closure. If the hindgut segment is not used in the initial reconstruction of the bowel, it is left as a mucous fistula.

Urinary Reconstruction

Modern Staged Reconstruction

The staged management of the urinary tract follows that used for the management of bladder exstrophy (Gearhart and Jeffs, 1991b). Once the bladder halves have been approximated posteriorly, the lateral edges are separated from the abdominal wall and brought together in the midline. As in the patient with classic exstrophy, placement of the bladder and posterior urethra deep into the pelvis remains a key factor in the successful surgical reconstruction of the urinary tract. Use of an AlloDerm patch to reduce the incidence of erosion of the interpubic stitch and prevent penopubic fistulization has been shown to be beneficial (Henderson et al., 2011). Inguinal hernias that are noted should be repaired at the time of closure. In genetic females and in genotypic male subjects undergoing gender reassignment, reconstruction should be performed to improve the appearance of the genitalia. Recent reports by Thomas et al. (2007) in a series using a staged approach found successful results in a series of seven patients, all with tethered cords.

Reconstruction of the external genitalia in the immediate postnatal period is performed to make the infant's appearance more congruent with the gender assigned. The psychiatric studies of children who have had gender assignment have fueled interest in male gender assignment if adequate unilateral or bilateral corporeal tissue is present (Reiner, 2004). Histologic studies indicate normal histology in the testes of male subjects who have had gender reassignment despite the presence of cryptorchidism (Mathews et al., 1999a). Past results of phallic reconstruction in male patients with limited penile tissue have been disappointing. Penile replacement with phalloplasty has now permitted successful reconstruction to be performed and allows most if not all genotypic males to be raised with a congruent sex (Lumen et al., 2008). Multiple flaps have been used successfully for phallic reconstruction (Bluebond-Langner and Redett, 2011; Massanyi et al., 2012). If male-to-female reassignment is deemed necessary, initial female genital reconstruction should bring the phallic halves together in the midline as a clitoris.

However, in instances with adequate corporeal tissue, either unilaterally or bilaterally, epispadias repair can be performed at around age 1 using the standards identified for the staged reconstruction. Vaginal reconstruction can be performed early in the genetic female patient. In gender-converted male patients who require reconstruction of a neovagina, delayed reconstruction is appropriate. Reconstruction may be performed by using a preserved hindgut segment or expanded perineal skin (Belloli et al., 1997). Long-term dilation of the neovagina may be required.

Pubic approximation permits abdominal wall closure and usually requires osteotomy and fixation with postoperative traction. External fixation and traction are typically maintained for 6 to 8 weeks to permit healing. Much like in CBE, sufficient pelvic immobilization after the closure of cloacal exstrophy is crucial for success. As shown in Table 31.6, the failure rate of bladder closures immobilized with external fixation and modified Buck's traction has been shown to be significantly lower than those immobilized with spica casts (Benz et al., 2017).

TABLE 31.6

Pelvic Immobilization After the Closure of Cloacal Exstrophy

METHOD OF IMMOBILIZATION	TOTAL CLOSURES		CLOSURES WITH OSTEOTOMY		CLOSURES WITHOUT OSTEOTOMY	
	TOTAL NO. (N=88)	NO. FAILED	TOTAL NO. (N=60)	NO. FAILED	TOTAL NO. (N=28)	NO. FAILED
Spica cast	46	33 (71.7)	18	9 (50)	28	24 (85.7)
External fixation with traction	43	4 (9.3)	43	4 (9.3)	0	0
P-value		<0.001		0.002		

Benz: 2018.

Role of Osteotomy

Infants who are medically stable may be considered for urinary tract reconstruction in the immediate postnatal period. **Osteotomy is indicated in all children with cloacal exstrophy at the time of bladder closure because of the wide diastasis that is invariably present** (Mathews et al., 1998). Osteotomy allows the pelvic ring, bladder, and abdominal wall to be closed without undue tension on the closure. Reduction in dehiscence and postoperative ventral hernias has been noted in patients treated with osteotomy. In a large series reported by Ben-Chaim et al. (1995c), significant complications occurred in 89% of patients who underwent closure of the cloacal exstrophy without osteotomy but in only 17% of patients who underwent osteotomy at the time of initial cloacal exstrophy closure. The patients who underwent osteotomy and those who did not were similar in terms of size of the omphalocele, presence of myelomeningocele, and time of primary closure. However, it is not surprising that osteotomy had no effect on eventual continence of patients with cloacal exstrophy.

Currently, combined bilateral anterior innominate and vertical iliac osteotomies are routinely used at our institution and have been attributed to a significant increase in the odds of a successful closure (Shah et al., 2014a; Tourchi et al., 2017). In fact, pelvic osteotomy increases the odds of successful closure by nearly sixfold (OR 5.8, 95% CI 1.7–19.6; $P = 0.004$). This approach does not require the patient to be repositioned on the operating table before commencement of bladder and abdominal wall closure. In addition, this method obviates the use of a posterior approach and any complication of the procedure related to the spinal or back closure. In a series of five patients with extreme pubic diastasis greater than 10 cm, Silver et al. (1999) described initial pelvic osteotomy and gradual pelvic closure of the fixator for 1 to 2 weeks, followed by abdominal wall and bladder closure. Closure was successful in all patients without technical problems or complications. This technique of staged pelvic closure may provide reliable initial secondary repair in patients with cloacal exstrophy in whom one-stage pelvic closure is not feasible, even with pelvic osteotomy. When compared with combined pelvic osteotomy with bladder closure, the staged approach results in comparable closure outcomes and overall complication rate (Inouye et al., 2014). An interpubic titanium bar has been added to permit stabilization of the pubic approximation and maintain the reduction in diastasis (Fig. 31.36) (Mathews et al., 2006). Because of the possible asymmetry that can be noted in the pelvic bones, care must be used when performing osteotomies and fixation. In patients who have lower extremity abnormalities, providing postoperative traction can also be challenging.

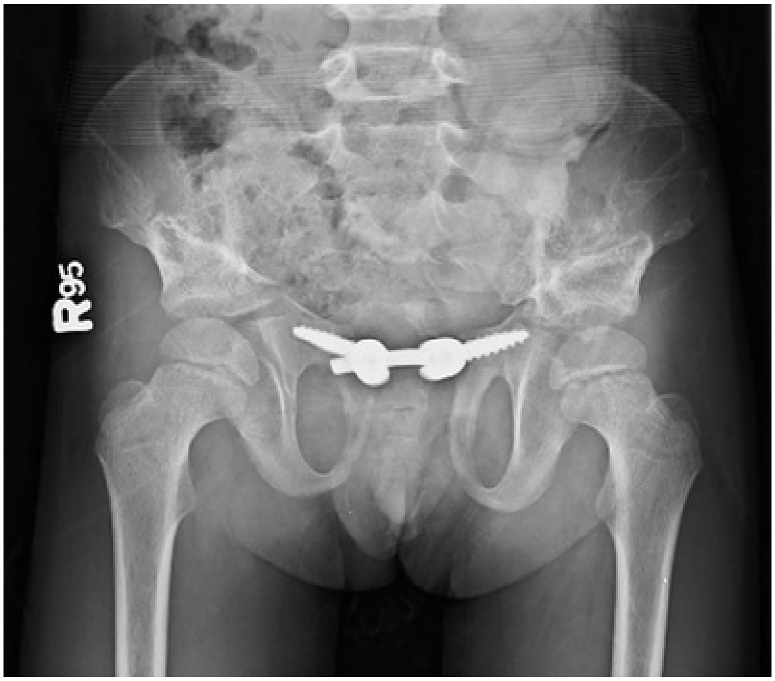

FIG. 31.36 Pubic apposition using titanium plate in cloacal exstrophy with extreme preoperative diastasis (8 cm) now with complete pelvic reduction.

Failure of urinary reconstruction in children with exstrophy can lead to lack of growth of the bladder and may require loss of the bladder template. Recently Shah et al. (2014a) identified potential causes for failure of the urinary reconstruction in a large series of children with cloacal exstrophy undergoing reconstruction at a tertiary medical center. They compared 26 patients (6,XY males, 8,XX females, and 12,XY gender-converted females) in whom prior urinary reconstruction had failed and who had been referred for reconstruction, with 34 patients (17,XY males, 12,XX females, and 5,XY gender-converted females) who underwent successful primary closure, to identify potential risk factors for failure.

In the first week of life 77% of patients with failed procedures had undergone closure, compared with 26% of those having undergone successful closure. In addition, only 31% of patients in whom closure had failed had osteotomy, compared with 82% of those who had undergone successful closure. In the patients with failed closure, 76% were immobilized with spica casts or mummy wraps. Among those in whom closure was successful, 56% were immobilized using modified Buck traction and external fixation, and an additional 20% were immobilized using Bryant traction with or without external fixation. Intersymphyseal plates to prevent separation of the pubis were used in 30% of patients with successful closure and in 50% of patients with successful reclosure;

92% of patients with successful reclosure had osteotomy. Use of a technique that staged the closure over a 2- to 3-week period after performance of the osteotomy by gradually cranking the fixator medially was also shown to be of benefit in providing a successful primary or secondary closure (Mathews et al., 2006).

Single-Stage Reconstruction

One stage reconstruction has been reported by Grady and Mitchell (1999), a procedure similar to that done for bladder exstrophy. If there is a large omphalocele or medical issues, they also recommend delay in attempting a single-stage reconstruction. In the authors’ experience with single-stage closures, we found a failure rate approaching 48%. This is a sharp contrast with the failure rate of a staged closure, 15%, which the authors recommend and routinely perform at their institution. In this situation, the conversion to a bladder exstrophy and subsequent reconstruction of the bladder and penis as a single step is performed. Lee et al. (2006) presented a limited experience in seven children with cloacal exstrophy who underwent reconstruction performed using a single-stage approach. There was one mortality before reconstruction. Six children who underwent reconstruction had dry intervals before toilet training. Some patients have required bladder neck injection to enhance continence. One child is voiding spontaneously and one child has undergone augmentation cystoplasty.

Failed Cloacal Exstrophy

The failure of the bladder closure associated with cloacal exstrophy is a tremendous setback in the reconstruction of this major birth defect. As such, ensuring successful primary bladder closure is paramount. In a large series examining the outcomes of bladder closure in cloacal exstrophy, it was found that a staged cloacal closure and the use of pelvic osteotomy were significant independent predictors of a successful closure outcome (Jayman et al., 2017). After the bladder closure, adequate immobilization secures the pelvis, contributing to the ultimate success of the closure. In our experience with closing cloacal exstrophy bladders, the use of external fixation, along with longitudinal traction for 6 weeks, is associated with high rates of success. On the other hand, immobilization with spica casts may not provide the pelvic stabilization necessary for a successful closure. Thus, the authors do not recommend such immobilization techniques in this difficult group of patients. Failed bladder closures also have financial ramifications to the patient and their families. The cost of cloacal exstrophy closure exceeds $136,000, and an additional $59,000 for attaining urinary continence. Patients who fail their primary closure accumulate significantly more total hospital charges than patients who experience successful closure (Goldstein et al., 2016). Fortunately, the complication rate of the secondary closure is thought to be similar to the complication rate of the primary closure (Friedlander et al., 2016).

Techniques to Create Urinary Continence

Urinary continence is possible in most children but usually requires bladder augmentation and the use of intermittent catheterization. Frequently, more than one procedure will be necessary over the lifetime of the patient. In a large series of cloacal exstrophy patients in which urinary continence was attempted, Maruf et al. found that a median of 2 (range 1–4) urinary continence procedures are typically performed to achieve a dry interval greater than 3 hours (Maruf et al., 2018). Revisions of the continent diversion were a frequent cause of requiring numerous procedures.

Multiple series by Gearhart and Jeffs (1991b), Mitchell et al. (1990), and Hendren (1992) have shown the applicability of modern techniques for lower tract reconstruction to help these patients achieve urinary continence. Enhancement of bladder capacity may be performed using a hindgut segment, if available; ileum; or stomach. Continence appears to be more difficult to achieve in male patients who undergo gender reassignment, and a continent stoma may be most applicable in this special group of patients (Mathews et al., 1998). In genetic female patients, successful continence has been achieved after Young-Dees-Leadbetter bladder neck reconstruction, but the majority of patients have required intermittent catheterization (Husmann et al., 1999). Similar findings were reported in a series by Mitchell et al. (1990). Husmann et al. (1999) reported that the success rate of Young-Dees-Leadbetter bladder neck reconstruction in the cloacal exstrophy population was closely related to the presence of coexisting neurologic abnormalities.

Urinary continence can be achieved in these individuals in many ways. An orthotopic urethra can be constructed from local tissue, vagina, ileum, stomach, or ureter. A catheterizable stoma can be constructed from ileum when enough bowel is present and fluid loss is not a problem. The bladder may be augmented with unused hindgut, ileum, or stomach. However, surgery to provide a continent urinary reservoir should be delayed until a method of evacuation can be taught and the child is old enough to participate in self-care. In our experience, the median age at which children are continent for urine is 11 years old (Maruf et al., 2018). The choice between a catheterizable urethra and an abdominal stoma depends on the adequacy of the urethra and bladder outlet, interest and dexterity of the child, and orthopedic status regarding the spine, hip joints, braces, and ambulation. A more recent evaluation of a large cohort of children with cloacal exstrophy (Suson et al., 2010) indicates that more than 50% of children (35 of 61) were able to achieve continence, 30 of 35 using intermittent catheterization through a continent stoma and the rest voiding or catheterizing via the urethra. An innovative approach is required to find a suitable solution for each individual patient according to the patient's bladder size and function and mental, neurologic, and orthopedic status.

Long-Term Issues in Cloacal Exstrophy

Because survival has become almost universal, the focus has changed in cloacal exstrophy to improving QoL. Improvement in functional outcomes has become the mainstay of improving the QoL. It must be stressed that although broad management strategies can be suggested, the management of patients with cloacal exstrophy must be individualized to maximize functional outcomes.

The factor most likely to lead to long-term disability is the level of the neurologic defect. Early aggressive evaluation and management of the neurologic issues with long-term close follow-up to evaluate for signs of cord tethering are critical to make sure that function can be preserved (McLaughlin et al., 1995).

Further management is most determined by the degree of neurologic deficit. When neurologic issues are minimal or absent, bowel pull-through and voided continence would be ideal. Ricketts et al. (1991) have presented a continence score that can be used in this group of children. Using a six-point scoring system to determine bowel and bladder continence (6 = best; 0 = worst), they evaluated 12 patients who had been managed over time. They had 7 patients with a continence score of 1 (colostomy and incontinent bladder) and only 1 patient who had a score of 5 (enema program and a continent bladder), attesting to the difficulties presented with surgical reconstruction.

Some children have required permanent ileostomy for management of their gut. Husmann et al. (1999) noted that patients undergoing permanent ileostomy, in comparison with terminal colostomy, had greater initial morbidity; however, bowel adaptation appeared to occur by age 3 years with resolution of the short gut syndrome in most. If patients with terminal ileostomy were aggressively managed with hyperalimentation, growth characteristics in the two groups were very similar. As noted earlier, bowel reconstructive techniques have permitted most children to avoid the long-term debility associated with short gut syndrome.

Attempts at phallic reconstruction in the past had minimal success because of the diminutive nature of the corpora in boys and the wide pubic separation. Modern reconstructive surgical techniques may allow some boys to have complete phallic reconstruction performed with forearm or other grafts. Fertility appears to be universally compromised in boys, but girls have normal fertility, and pregnancy has been reported. Girls have higher degrees of cervical prolapse when compared with their counterparts with bladder exstrophy.

Summary

Evolution in management of cloacal exstrophy has permitted near-universal survival with significant improvement in cosmetic and functional outcomes. Debate continues regarding the issue of gender reassignment, and long-term data are still accruing on the best strategy for management. Continence can be achieved with appropriate reconstruction and the use of intermittent catheterization. Despite the extensive malformations noted, many patients have lived fruitful lives.

Key Points: Cloacal Exstrophy—Priorities in Management

- Medical stabilization
- Evaluation of associated anomalies
- Colonic functionalization
- Separation of bladder from the gastrointestinal tract
- Functional genital reconstruction

Dedication

This chapter is dedicated to Dr. Richard Grady, respected colleague and friend, who left us too soon.

Acknowledgment

The authors gratefully acknowledge the role of Dr. Mahir Maruf in editing this chapter.

Prune-Belly Syndrome

Francisco Tibor Dénes MD, PhD, Roberto Iglesias Lopes MD, PhD

Prune-belly syndrome (PBS) includes a constellation of anomalies with variable degrees of severity. The three major findings are deficiency of the abdominal musculature, bilateral intra-abdominal testes, and anomalous urinary tract. The urinary tract is characterized by variable degrees of hydronephrosis, renal dysplasia, dilated tortuous ureters, enlarged bladder, and dilated prostatic urethra. Additional associated anomalies involve the respiratory tract, gastrointestinal tract, cardiac system, and musculoskeletal system. There is a broad spectrum of severity of the syndrome: some children do not survive the newborn period and others are minimally affected. The most important determinant of long-term survival is usually the severity of the urinary tract anomaly, in particular, the degree of renal dysplasia.

The characteristic abdominal wall was first described by Frölich in 1839, and the full triad of anomalies by Parker in 1895. Osler's vivid description of the abdominal wall of an infant with the characteristic findings led to the term *prune-belly syndrome* (Osler, 1901). Other names that have been applied to this syndrome include *triad syndrome, Eagle-Barrett syndrome,* and *abdominal musculation syndrome* (Eagle and Barrett, 1950; Greskovich and Nyberg, 1988).

The incidence of PBS has been reported to be 1 in 29,000 to 1 in 40,000 live births, similar to that of bladder exstrophy (Williams and Burkholder, 1967); **95% occur in males** (Wheatley et al., 1996). Females with PBS have the abdominal wall deficiency and urinary tract dysmorphism without any gonadal anomaly (Rabinowitz and Schillinger, 1977; Reinberg et al., 1991b). A higher incidence is noted in twins, blacks, and children born to younger mothers. In developed countries, the incidence appears to be declining because of prenatal diagnosis and termination of pregnancy. In a review reported in 2010 by Routh et al. of the Kids' Inpatient Database (United States based) evaluating newborns with PBS during their initial hospitalization between 2000 and 2006, the weighted incidence estimate was 3.8 cases per 100,000 live births.

Genetics

The high male-to-female ratio, occasional occurrence in male siblings and cousins, and increased occurrence in twins suggest a genetic basis for PBS. Yet most cases are sporadic and have a normal karyotype. One in 23 children with PBS is the product of a twin pregnancy (Ives, 1974). However, the majority of reported twins have been discordant for PBS, evidence against a genetic cause. It has been suggested that the cause in twins may be due to an uneven distribution of mesenchymal tissue at a critical time of primitive streak development during the third week of embryogenesis (Coplen et al., 1996). There is a reported association with Turner syndrome, monosomy 16, trisomy 13, and trisomy 18 (Amacker et al., 1986; Hoagland and Hutchins, 1987). A variety of inheritance patterns have been proposed, including X-linked recessive (Frydman et al., 1993), a two-step autosomal dominant mutation (Riccardi and Grum, 1977), and polygenetic transmission (Adeyokunnu and Familusi, 1982; Garlinger and Ott, 1974; Lockhart et al., 1979). A report by Ramasamy et al. (2005) suggested a sex-influenced autosomal recessive mode of inheritance in familial PBS. The consensus, however, remains that an associated chromosomal abnormality is the exception rather than the rule because most have a normal karyotype. Other reports have noted an association between PBS and Beckwith-Wiedemann syndrome (Silengo et al., 2002; Sinico et al., 2004).

Embryology

Several theories about the embryogenesis of PBS have been proposed. However, because there is no experimental model that can be used to test these theories, the exact mechanism remains elusive. The four main theories are (1) an early in utero posterior urethral obstruction resulting in severe dilation of urinary tract and possible fetal ascites and oligohydramnios (Beasley et al., 1988; Pagon et al., 1979; Strumme, 1903; Wheatley et al., 1996); (2) a primary defect in the lateral plate mesoderm, which is the precursor of the ureters, bladder, prostate, urethra, and gubernaculum (Gonzalez et al., 1990; Ives, 1974); (3) an intrinsic defect of the urinary tract leading to ureteral dilation and fetal ascites (Cazorla et al., 1997; Monie and Monie, 1979; Nakayama et al., 1984; Smythe, 1981; Symonds and Driscoll, 1974); and (4) a yolk sac defect (Stephens, 1983; Stephens and Gupta, 1994). None of these theories has universal acceptance, and there is some overlap between them.

Clinical Features of Prune-Belly Syndrome

Genitourinary Anomalies

Kidneys

A spectrum of renal abnormalities extends from normal renal parenchyma to dysplasia (Figs. 32.1 and 32.2). The more severely dysplastic kidneys are generally associated with bladder outlet obstruction in which there has not been decompression through a patent urachus (Potter, 1972). **Dysplasia is present in 50% of cases; however, it may vary in degree and laterality (Rogers and Ostrow, 1973; Stephens, 1983). Renal dysplasia in PBS of the Potter type II and IV varieties is seen.** The Potter type II variety with few nephrons and parenchymal disorganization is more indicative of a renal mesenchymal defect, whereas the Potter type IV with cortical and tubular cysts is associated with outlet obstruction (Wigger and Blanc, 1977).

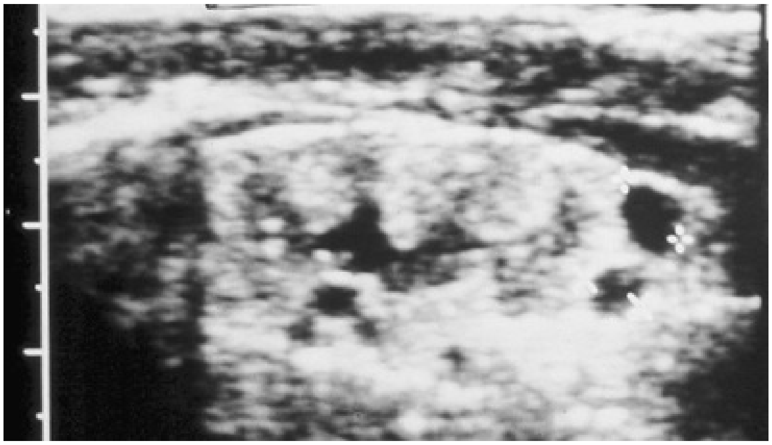

FIG. 32.1 Ultrasound scan of a kidney of a newborn with prune-belly syndrome demonstrating markedly echogenic renal parenchyma and cortical cysts indicative of renal dysplasia.

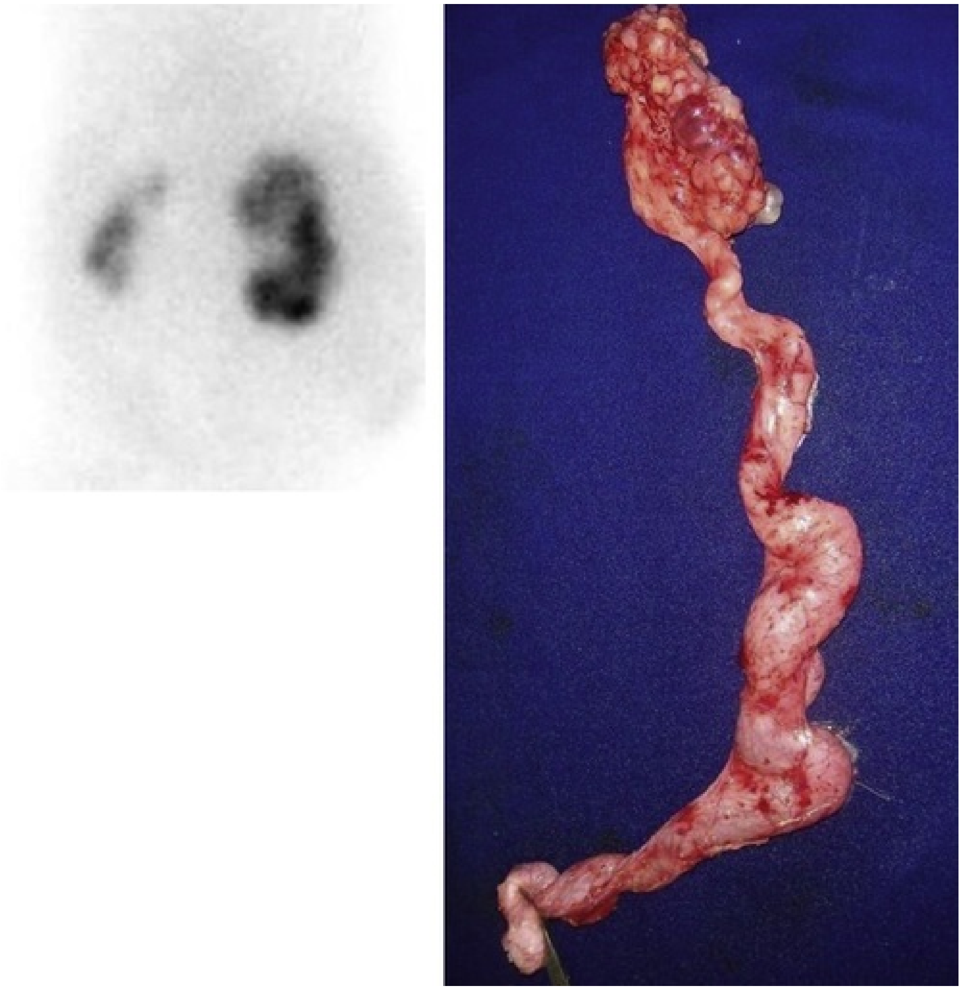

FIG. 32.2 Unilateral renal dysplasia with dilation and tortuosity of the ureter in a patient with prune-belly syndrome.

The renal collecting system is characteristically dilated, often to a severe degree. The degree of dilation, however, does not correlate with the degree of renal dysplasia. Calyceal morphology may be well preserved, even in the presence of massively dilated ureters and renal pelvis (Berdon et al., 1977). Some patients may have one severely dysplastic or dilated kidney, and the other kidney may have only mild abnormalities. Ureteropelvic junction obstruction can occur on a primary or secondary basis; however, nonobstructive hydronephrosis is the rule (Woodard and Parrott, 1978b). It is renal infection rather than obstruction that poses the greatest risk to renal function.

Ureters

The ureters are typically dilated, tortuous, and redundant. The proximal (upper) portions of the ureters are usually less abnormal than the distal

segments, although massive dilation and stenosis can occur at all levels (Fig. 32.3). In many patients the severity of the urinary tract abnormalities is not proportional to the degree of flaccidity of the abdominal wall. Histologic sectioning demonstrates lack of smooth muscle cells and increase in fibrous connective tissue. Generally, there are more normal-appearing smooth muscle cells in the proximal segments (Palmer and Tesluk, 1974; Stephens, 1983). This fact is critical when ureteral reconstruction is undertaken. The ratio of collagen to smooth muscle cells in prune-belly ureters has been noted to be elevated, especially in refluxing ureters (Gearhart et al., 1995). A decreased number of thick and thin myofibrils noted on ultrastructural examination is thought to contribute to the poor peristalsis (Berdon et al., 1977; Stephens, 1983).

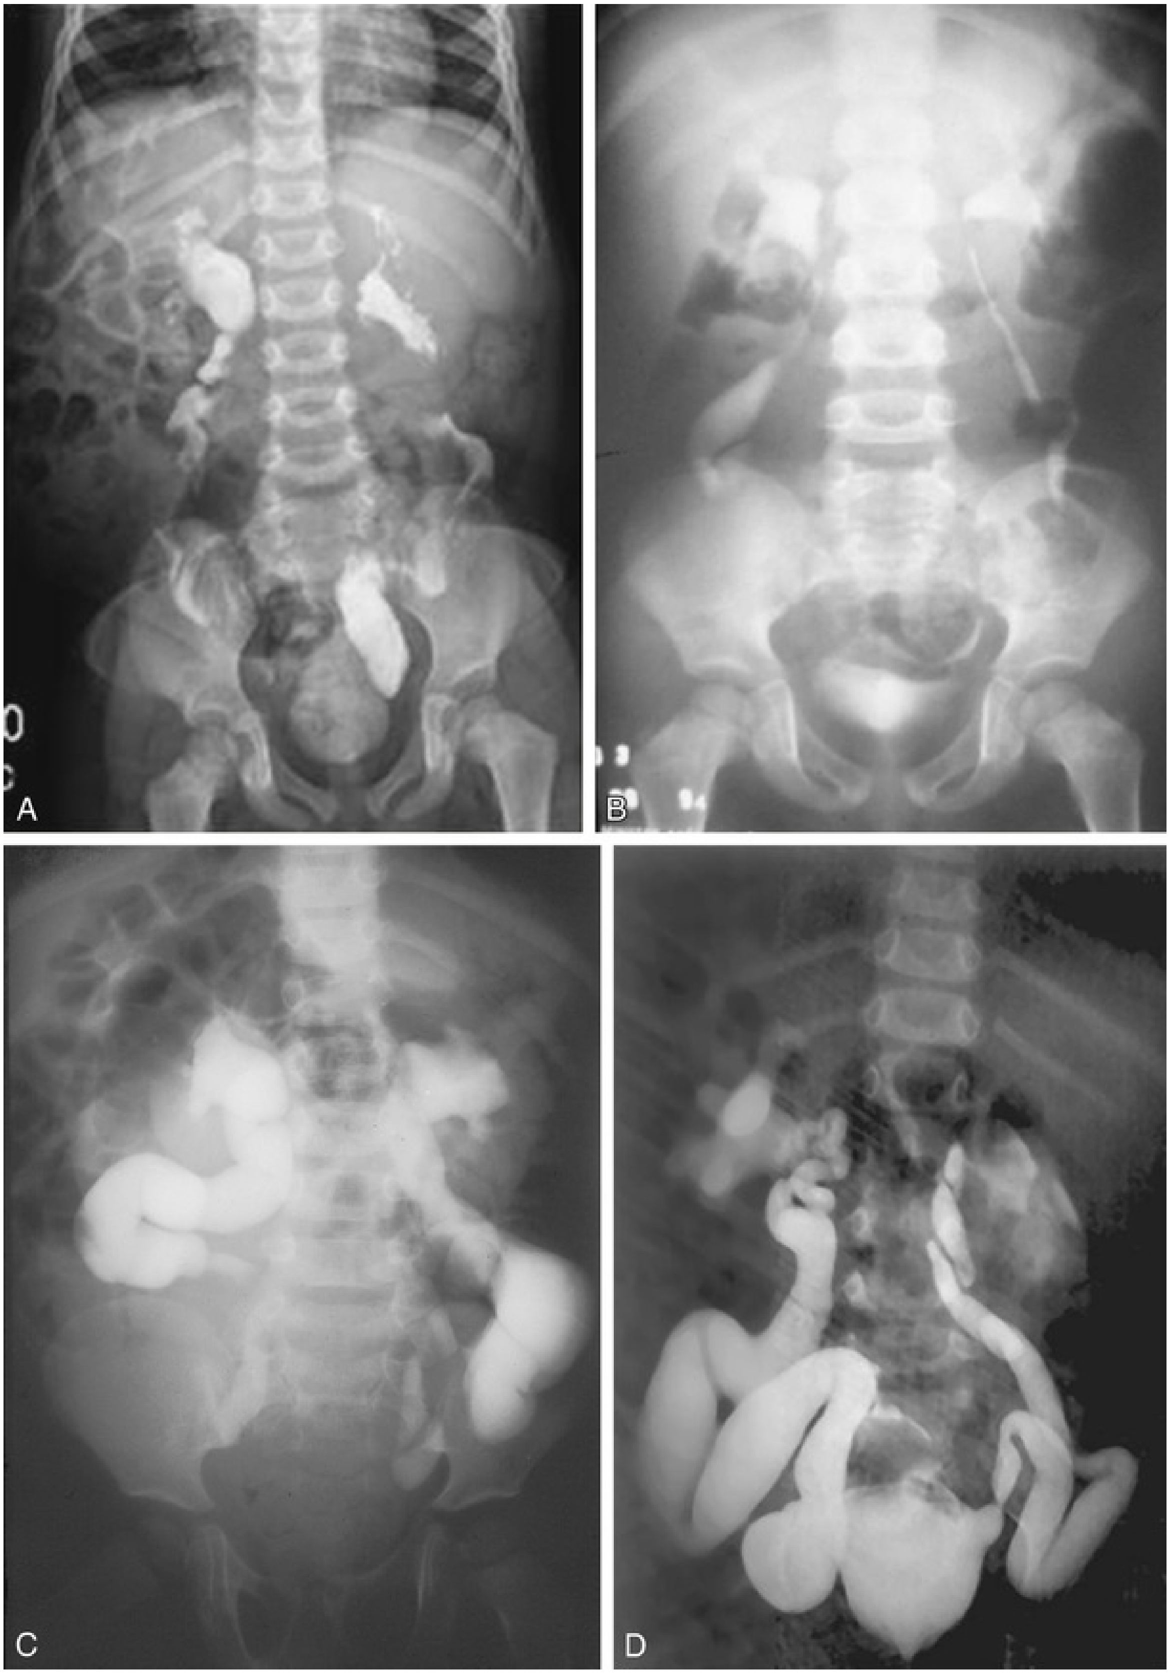

FIG. 32.3 Excretory urogram (A to C) demonstrating the variability in the

degree of hydroureteronephrosis in prune-belly syndrome. Note the preservation of calyceal architecture, despite severe ureteral dilation in C. (D) Dilated tortuous refluxing ureters as seen on a voiding cystourethrogram.

Vesicoureteral reflux is present in 75% of children with PBS (Berdon et al., 1977; Fallat et al., 1989) (Fig. 32.4). Obstruction is not common but has been reported at the ureteropelvic and ureterovesical junctions (Manivel et al., 1989; Moerman et al., 1982; Wigger and Blanc, 1977).

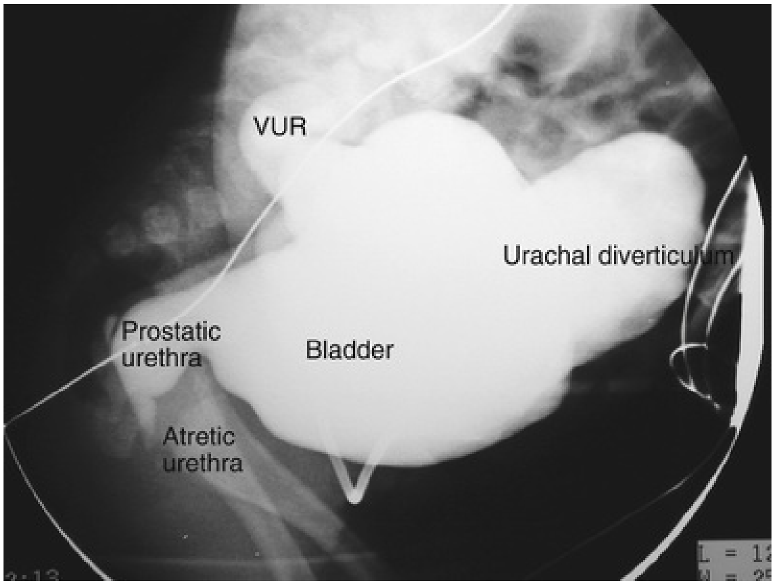

FIG. 32.4 Voiding cystourethrogram of a child with prune-belly syndrome demonstrating posterior urethral dilatation, urethral atresia, urachal diverticulum, and vesicoureteral reflux *(VUR)*.

These large ureters may have ineffective peristalsis because of poor ureteral wall coaptation. The ureteral conduction wave reaches a reduced smooth muscle cell population of poor contractile potential related to reduced myofibrils, often separated by patches of collagen, with the resulting bolus of urine reaching more dilated and nonpropulsive ureteral segments as it progresses toward the bladder (Woodard and Smith, 1998). This can be seen fluoroscopically as ineffective peristalsis, resulting in upper tract stasis, which may lead to infection (Nunn and Stephens, 1961; Williams and Burkholder, 1967).

Bladder

The bladder usually appears massively enlarged with a pseudodiverticulum at the urachus (Fig. 32.5). The urachus is patent at birth in 25% to 30% of children (Lattimer, 1958; Stephens and Gupta, 1994; Wigger and Blanc, 1977). Despite being very thick, the bladder wall is smooth, unlike that seen in obstructed bladders. Histologically, the bladder has an increased ratio of collagen to muscle fibers in the absence of obstruction (Workman and Kogan, 1990). However, smooth muscle hypertrophy can be seen in the obstructed prune bladder (Perlmutter, 1976). The pelvic distribution of ganglion cells has been shown to be normal (Burke et al., 1969; Nunn and Stephens, 1961); however, a decrease in α_{1a}-adrenoceptor immunostaining intensity has been documented (Schneider-Monteiro et al., 2010). A recent quantitative microscopic study showed that the bladder of PBS fetuses had lower concentrations of smooth muscle fibers, collagen type III and nerves, structural alterations that can be involved in the functional bladder abnormalities later in life (Julio Junior et al., 2017). The trigone is splayed with the ureteral orifices displaced laterally and superiorly, possibly contributing to the high incidence of vesicoureteral reflux (Williams and Burkholder, 1967).

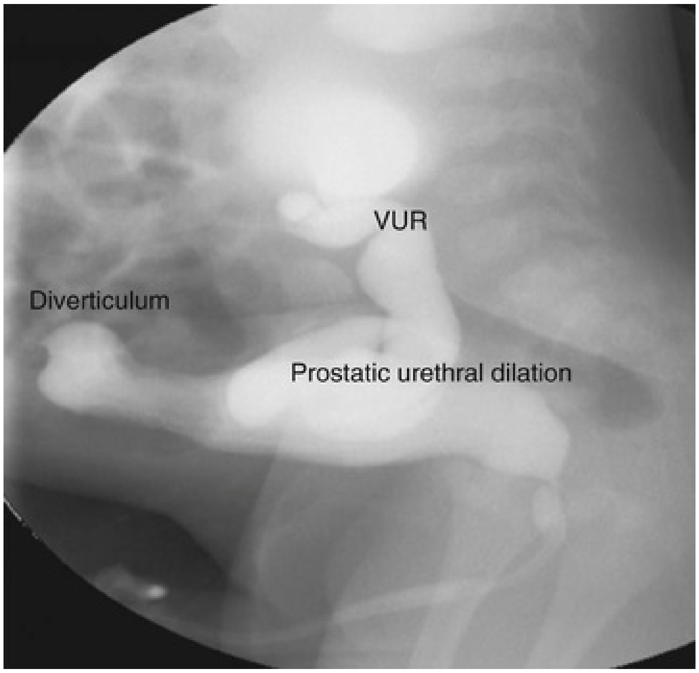

FIG. 32.5 Voiding cystourethrogram of a child with prune-belly syndrome demonstrating prostatic urethral enlargement related to a hypoplastic prostate and also demonstrating a urachal diverticulum and vesicoureteral reflux *(VUR)*.

On voiding, the bladder neck opens widely into a dilated prostatic urethra (see Fig. 32.5). Urodynamic assessment generally shows normal compliance; however, there is a delayed first sensation to void and a large capacity (Snyder et al., 1976). The ability to empty the bladder is variable, with some emptying well and others carrying a significant postvoid residual. This is thought to be due to a relative outlet obstruction and the inability of the bladder to generate sufficient pressure with a detrusor contraction. When the relative outflow resistance prevents effective bladder emptying, the term *unbalanced voiding* is used (Kinahan et al., 1992; Snyder et al., 1976). **Despite these limitations, about 50% of prune-belly patients void spontaneously with normal voiding pressures, normal flow rates, and low postvoid residuals** (Kinahan et al., 1992; Nunn and Stephens, 1961). However, as Kinahan et al. (1992) demonstrated, deterioration of balanced voiding can occur with growth, resulting in significant postvoid residuals, which emphasizes the need for periodic assessment.

Key Points: Clinical Features

- Kidney dysplasia occurs in half of the patients.
- Hydroureteronephrosis is often to a severe degree; however, the calyceal morphology may be well preserved.
- The proximal portion of the ureters has more normal muscle than the distal portions.
- Vesicoureteral reflux is present in most patients.
- The bladder is large with a pseudodiverticulum at the urachus and a wide bladder neck opening into a dilated prostatic urethra.

Prostate and Accessory Sex Organs

The dilation of the posterior urethra is due to prostatic hypoplasia, probably related to abnormal mesenchymal-epithelial development (Stephens and Gupta, 1994). Histologically, there are few prostatic cellular elements, with a reduction of epithelial and smooth muscle cells and an increase in connective tissue cells (Moerman et al., 1982; Popek et al., 1991; Stephens and Gupta, 1994). Various obstructive lesions of the distal posterior urethra have been described—urethral atresia, valves, urethral stenosis, urethral membrane, and urethral diverticulum—

and are thought to occur in 20% of cases (Hoagland and Hutchins, 1987). Stephens (1983) described an angulation of the urethra during voiding, referred to as *type IV valves*, which results from lack of prostatic parenchymal tissue. Prostatic hypoplasia, the cause of which is controversial, is thought to be a factor in the ejaculatory failure of patients with PBS (Volmar et al., 2001). The vas deferens and seminal vesicles are often atretic, although either may be dilated or thickened (Stephens and Gupta, 1994). Hypoplasia and agenesis of the prostate and seminal vesicle were frequent findings in a study made with magnetic resonance imaging in adult patients with PBS (Dénes et al., 2017). **The epididymis may be poorly attached to the testis, as is seen commonly in abdominal undescended testes. There may also be lack of continuity between the efferent ductules and the rete testis.** Ejaculation occurs usually in a retrograde fashion because of an incompetent bladder neck.

Anterior Urethra

Although the anterior urethra of the PBS child is usually normal, several anomalies of the urethral segment have been reported; the most common are urethral atresia or hypoplasia and megalourethra (Kroovand et al., 1982; Perrotin et al., 2001). **Unless it is associated with a patent urachus, urethral atresia is often lethal** (see Fig. 32.4). It has been postulated that urethral atresia or hypoplasia occur because the urethra is unused rather than malformed. Spontaneous bladder rupture with fistula formation has also been reported (Reinberg et al., 1993).

PBS is associated with two variations of megalourethra (Mortensen et al., 1985; Shrom et al., 1981). The fusiform type is a deficiency of the corpus cavernosum, as well as the spongiosum, and the scaphoid variety is a deficiency of the spongiosum only with preservation of the glans and corpora cavernosa (Fig. 32.6). With the scaphoid variety, the ventral urethra dilates with voiding, whereas with the fusiform variety the entire phallus dilates with voiding. The fusiform variety is thought to result from a mesenchymal deficiency of the urethral folds, whereas the scaphoid variety results from a mesenchymal deficiency of the urethral supportive tissues (Dorairajan, 1963). Megalourethra is more commonly seen in PBS than any other syndrome (Appel et al., 1986). Transient in utero obstruction of the junction between the glanular and penile urethra has been proposed to cause megalourethra.

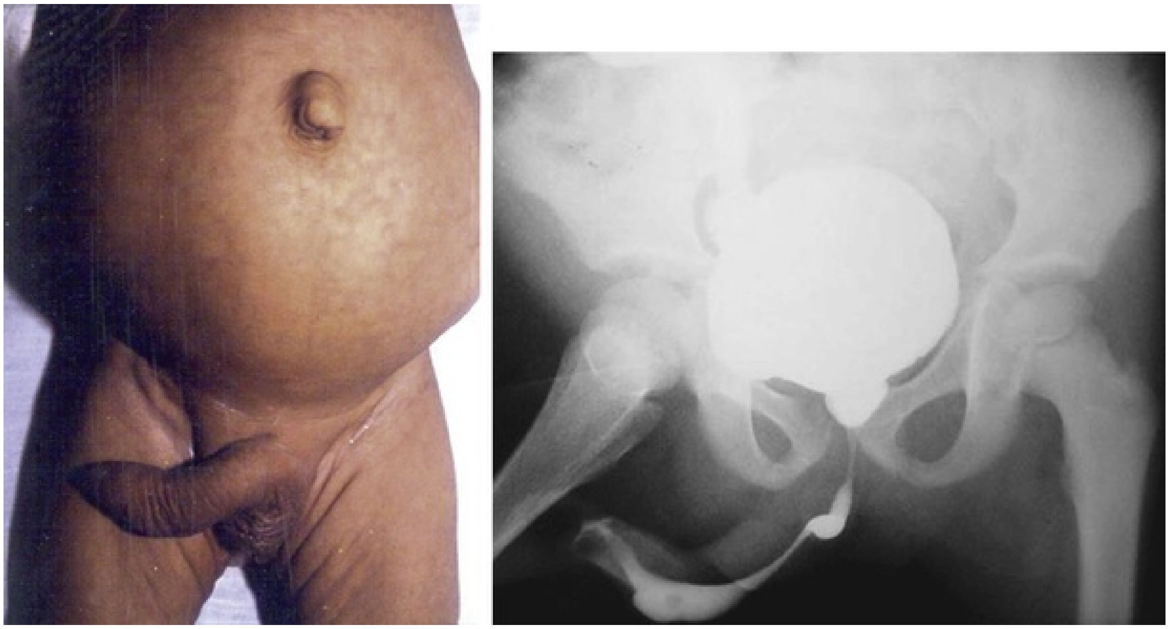

FIG. 32.6 Scaphoid megalourethra and posterior urethral dilation.

Testes

Bilateral intra-abdominal testes lying over the iliac vessels and adjacent to the dilated ureters are the most typical findings (Fig. 32.7). Although mechanical forces such as a distended bladder and intra-abdominal pressure have been implicated in maldescent of the testes (Hutson and Beasley, 1988; Kaplan et al., 1986), the fact that some patients with the typical urinary tract and abdominal musculature anomalies (because of incomplete presentation of the syndrome in the *pseudo prune* patients) may have descended testes raises some doubt about pure mechanical factors.

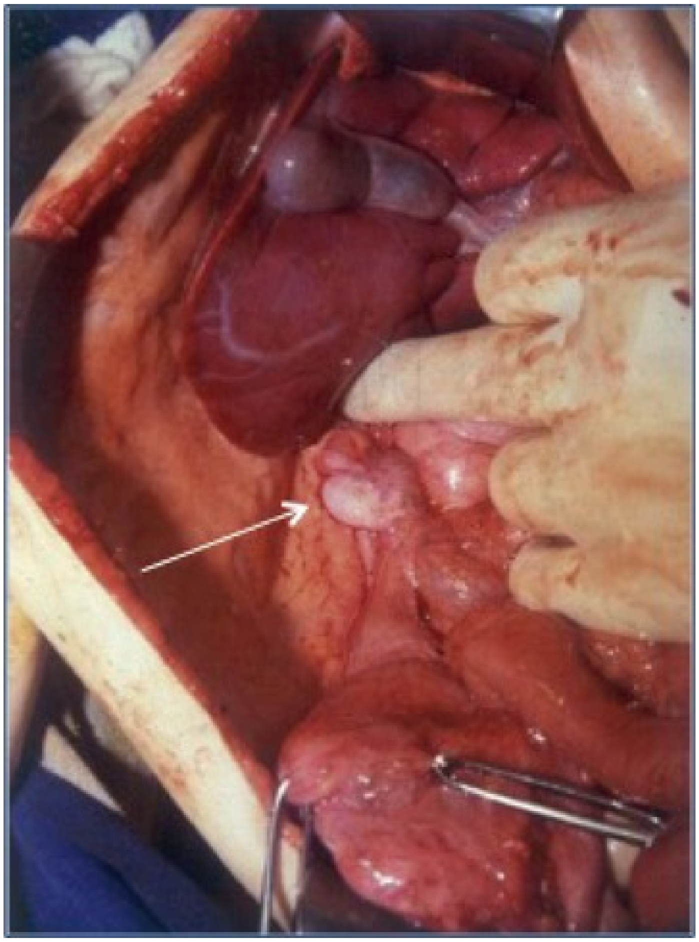

FIG. 32.7 Cryptorchid right testis lying high in the abdominal cavity *(arrow)*.

Pak et al. (1993) compared the histology of the testes in patients with PBS with that of non-prune-belly intra-abdominal testes and that of age-matched control subjects. **They found no difference in germ cell counts, Ad spermatogonia, and Leydig cells between PBS testes and non-PBS intra-abdominal testes. However, because germ cell counts in patients with PBS who are younger than 1 year are similar to those of age-matched controls, the implication is that the environmental state of the abdomen is a major factor in their later spermatogenic potential** (Coplen et al., 1996; Nunn and Stephens, 1961). This mirrors findings of Nunn and Stephens (1961) of normal germinal epithelium of fetal and newborn PBS testes. Alternatively, Orvis et al. (1988) noted decreased numbers of spermatogonia and Leydig cell hyperplasia in fetal PBS testes, implying an intrinsic testicular abnormality. Another study also showed a lower concentration of Leydig cells in the testes of PBS fetuses (Favorito et al., 2017).

Azoospermia is usually found in adult patients with PBS, and no patient with PBS has been reported to have spontaneously fathered a child (Woodhouse and Snyder, 1985). The infertility is thought to be due to a combination of testicular histologic abnormalities, structural defects of the ducts, and prostatic abnormalities also associated to retrograde ejaculation (Tayakkanonta, 1963). More recently, paternity with normal live births was documented in adult patients with classic PBS, achieved by sperm retrieval techniques and intracytoplasmic sperm injection (Fleming et al., 2013; Kolettis et al., 1999). Normal pregnancy with assisted vaginal delivery was also described in a female patient with the syndrome (Hillman et al., 2012).

Three cases of testis tumor have been reported (Parra et al., 1991; Sayre et al., 1986; Woodhouse and Ransley, 1983). Massad et al. (1991) described histologic testicular patterns similar to those in intratubular germ cell neoplasia in three infants. Although the risk of malignancy may be relatively low considering the lack of germinal epithelium (Uehling et al., 1984), it is clear that placement of the testis in the scrotum and long-term follow-up are necessary to reduce the risk of testicular malignancy and enhance detection.

Extragenitourinary Abnormalities

Of all children with PBS, 75% have non–urinary tract abnormalities (Geary et al., 1986). After the obvious abdominal wall defect, the most common issues are cardiac, pulmonary, and orthopedic (Table 32.1). In addition to these organ specific morbidities, nearly 50% of children with PBS are born premature, which significantly contributes to comorbidities.

TABLE 32.1

Nonurologic Associated Abnormalities in Children With Prune-Belly Syndrome

PBS, Prune-belly syndrome.

Data from Routh JC, Huang L, Retik AB, Nelson CP: Contemporary epidemiology and characterization of newborn males with prune belly syndrome. *Urology.* 76:44–48, 2010.

Abdominal Wall Defect

The appearance of the abdominal wall gives newborns with PBS their most characteristic feature (Fig. 32.8). Although in some cases the musculature of the abdominal wall may be totally absent (Manivel et al., 1989), most commonly there is uneven involvement with the medial and inferior muscular segments typically most deficient (Mininberg et al., 1973; Randolph, 1977). The appearance at birth is that of wrinkled, redundant skin with an abdomen that bulges in the flanks. One may be able to discern intra-abdominal organs through the thinned abdominal wall. **The most severely affected areas may have skin, subcutaneous fat, and a single fibrous layer on the peritoneum** (Baird and Sadovnick, 1987; Mininberg et al., 1973). **Randolph conducted electromyographic mapping and demonstrated the inferior and medial segments to be most consistently affected** (Randolph et al., 1981a). Electron microscopy has demonstrated a nonspecific pattern of myofilament disarray, Z-line disorganization, and mitochondrial proliferation (Afifi et al., 1972; Randolph et al., 1981b; Woodard and Smith, 1998). The fact that normal spinal anterior horn cells have been shown rules out a neuropathic cause for the muscular deficiency (Nunn and Stephens, 1961). However, the muscular deficiency is typically inconsistent and patchy, and as mentioned earlier, may be disproportional to the abnormalities of the urinary tract.

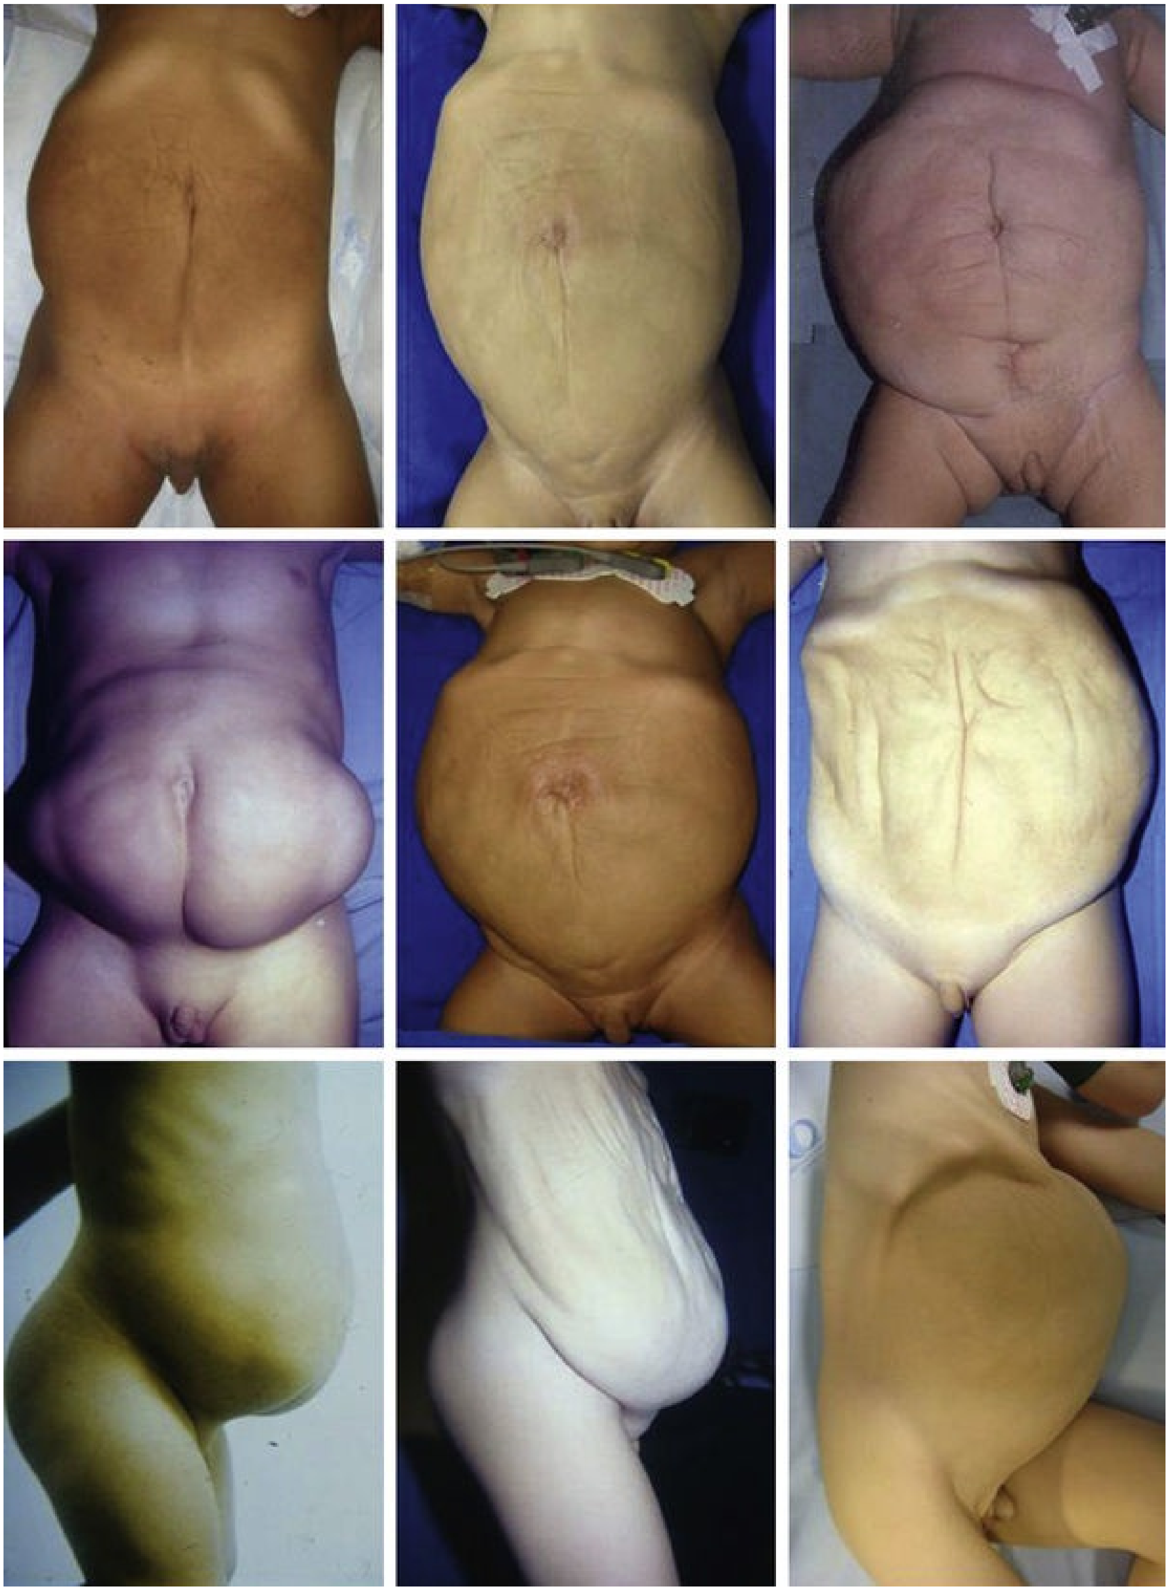

FIG. 32.8 The variability of the abdominal wall defect in patients with prune-belly syndrome.

As the patients grow, some of them show improved abdominal tonus and appearance with fewer wrinkles, whereas in others the abdomen takes on more of a pot-belly appearance (Fig. 32.9). Gait is usually not affected, although it may be delayed, and the children tend to roll to their side and use their arms to sit from a supine position. The poor support of the lower chest wall results in flaring of the costal margin (Woodard and Smith, 1998). These children are more vulnerable to respiratory illness because their cough effectiveness is compromised. In spite of these abdominal wall issues, Woodard and Smith (1998) reported good wound healing without a tendency toward infections or incisional hernias.

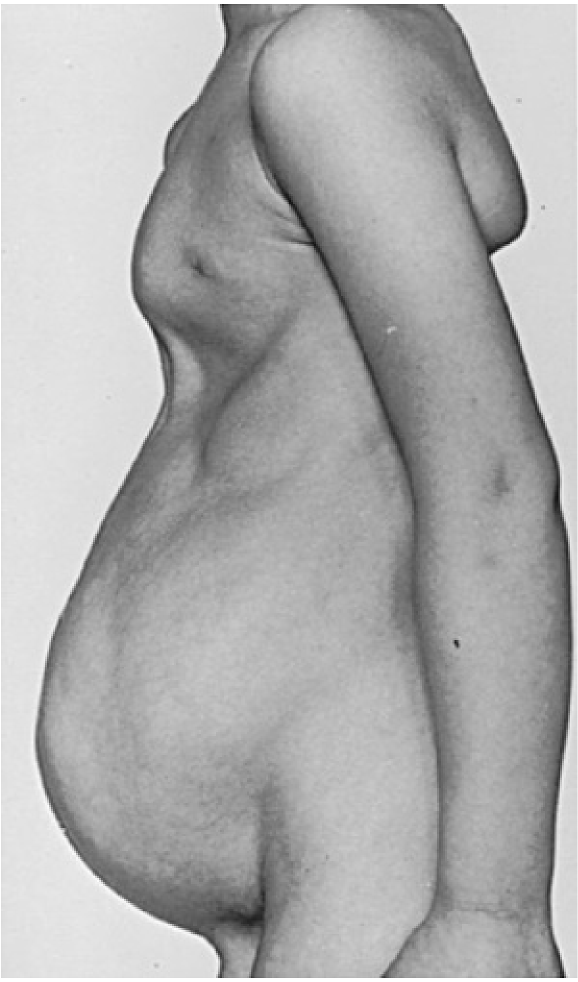

FIG. 32.9 Older child with prune-belly syndrome, showing the absence of wrinkling, the "pot-belly" appearance, and the consequent deformity of the lower ribs.

Cardiac Anomalies

Cardiac anomalies such as patent ductus arteriosus, atrial and ventricular septal defects, ventricular septal defect, and tetralogy of Fallot occur in 10% of children with PBS (Adebonojo, 1973). Cardiac abnormalities at birth may take precedence over urologic issues.

Pulmonary Abnormalities

Pulmonary difficulties can be observed at any age in patients with PBS. **Pulmonary hypoplasia can result from severe oligohydramnios related to renal dysplasia or severe bladder outlet obstruction and may result in newborn demise. In addition, pneumothorax and pneumomediastinum can be seen with or without pulmonary hypoplasia** (Skoog, 1992). **Significant pulmonary difficulties have been reported in 55% of PBS survivors** (Geary et al., 1986, Routh, 2010). In nearly half of newborns with PBS, intubation and mechanical ventilatory support will be required with its attendant morbidities (Routh et al., 2010).

The lack of ability to generate significant intra-abdominal pressure may contribute to pneumonia and lobar atelectasis (Alford et al., 1978; Ewig et al., 1996). Acute respiratory illnesses or anesthetic procedures can easily lead to respiratory infections and insufficiency in the patient with PBS, who may have underlying chronic bronchitis from repeated respiratory problems and impaired cough mechanism. Many patients demonstrate significant restrictive lung disease secondary to associated musculoskeletal abnormalities such as scoliosis and rib cage abnormalities, most commonly *pectus excavatum* (Coplen et al., 1996; Fig. 32.10).

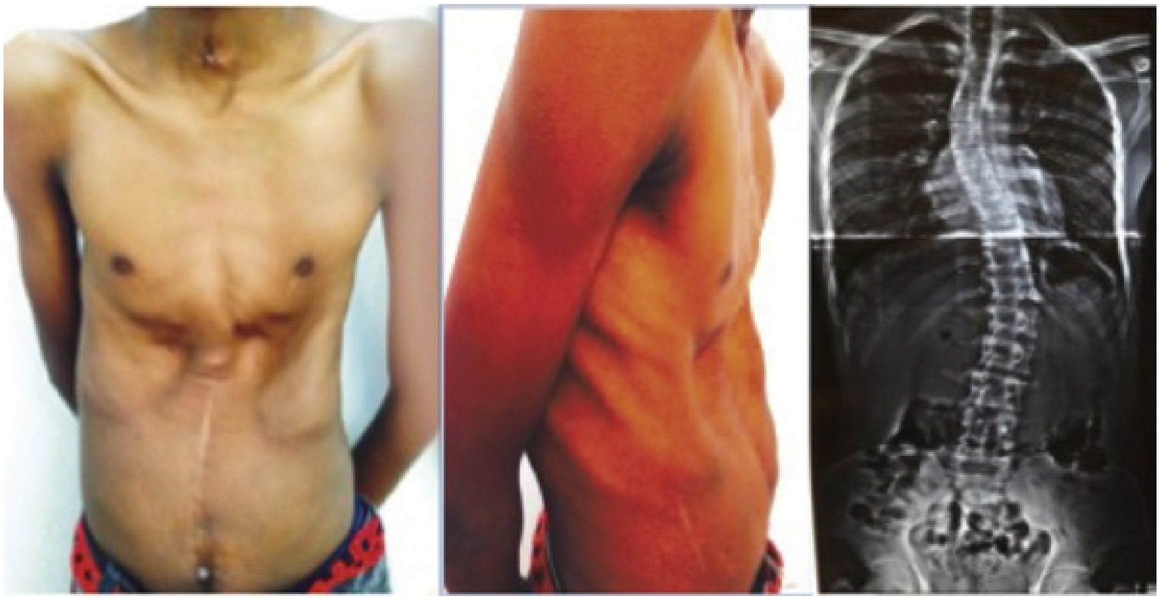

FIG. 32.10 Older child with *pectus scavatum* and scoliosis (note scars from previous tracheostomy and abdominoplasty, as well as a umbilical appendicovesicostomy).

Gastrointestinal Abnormalities

In at least 30% of cases, gastrointestinal anomalies are observed. The majority of the anomalies result from incomplete rotation of the midgut giving way to a wide mesentery, which results in increased bowel mobility with intestinal malrotation, volvulus, atresias, and stenosis (Silverman and Huang, 1950; Wright et al., 1986). Splenic torsion related to abnormal mesenteric fixation has also been reported (Heydenrych and Du Toit, 1978; Teramoto et al., 1981, Tran et al., 2013). Omphalocele, gastroschisis, situs inversus abdominis, VACTERL (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities) and anorectal abnormalities have been reported (Awad and Lall, 2016; Morgan et al., 1978; Petersen et al., 1972; Ramagopal et al., 2016; Short et al., 1985; Walker et al., 1987; Wilbert et al., 1978; Fig. 32.11). With a limited ability to generate intra-abdominal pressure as a result of the abdominal muscular hypoplasia, constipation becomes a lifelong problem and may lead to acquired megacolon (Woodard and Smith, 1998).

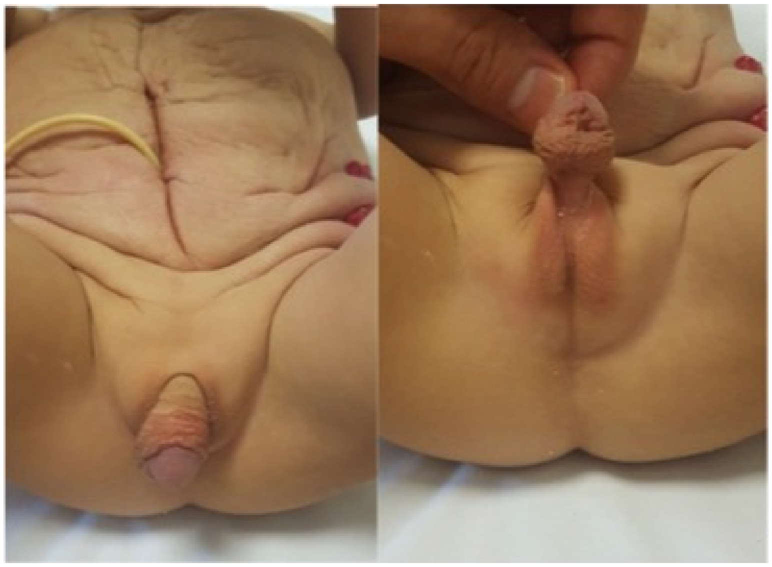

FIG. 32.11 Patient with prune-belly syndrome and associated anal imperforation.

Orthopedic Abnormalities

Orthopedic abnormalities, ranging in incidence up to 65% in contemporary series, are second in frequency to those of the genitourinary tract and abdominal wall (Grimsby et al., 2015). Some think the musculoskeletal defects result from the abnormal mesenchymal development at 6 weeks of gestation (Loder et al., 1992). Green et al. (1993), however, pointed out that because many of the deformities are unilateral, the most likely cause is the compressive effect of oligohydramnios. Oligohydramnios may also result in *talipes equinovarus* (26%), hip dysplasia (5%), and congenital scoliosis (4%) (Woodard and Smith, 1998). Dimpling of the lateral aspect of the knees is a common finding in oligohydramnios and is frequent in patients with PBS (Fig. 32.12). It has also been proposed that a distended bladder that impinges on the external iliac vessels may compromise the blood supply to the lower extremities and, in severely affected cases, result in lower extremity hypoplasia, absence, or amputation (Green et al., 1993; Smith, 1913) (Fig. 32.13). Some malformations tend to manifest or worsen with growth, such as renal osteodystrophy, dislocation of the hip, scoliosis, and pectus excavatum or carinatum (Green et al., 1993; Loder et al., 1992).

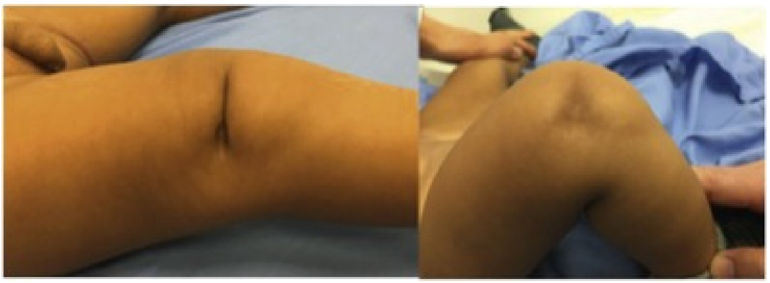

FIG. 32.12 Knee dimple (right leg), a characteristic finding in patients with the prune-belly syndrome.

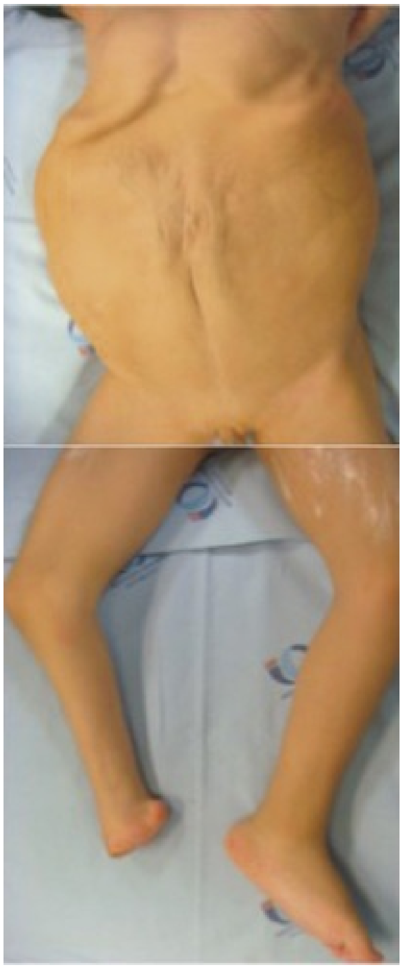

FIG. 32.13 Right foot amputation in a patient with the prune-belly syndrome.

Oral Abnormalities

There are reports on oral manifestations of the syndrome, including dental and bone abnormalities (Basso et al., 2012; Pessoa and Galvão, 2013).

Key Points: Associated Abnormalities

- Megalourethra is more commonly seen in PBS than any other syndrome. With the scaphoid variety, the ventral urethra dilates with voiding, whereas with the fusiform variety, the entire phallus dilates with voiding.
- Infertility is thought to be due to a combination of testicular histologic abnormalities, structural defects of the ducts, and prostatic abnormalities and retrograde ejaculation.
- Pulmonary hypoplasia can result from severe oligohydramnios related to renal dysplasia or severe bladder outlet obstruction and may result in newborn demise.
- Although one of the hallmarks of the syndrome, the abdominal flaccidity has no direct relationship with the intensity of the urologic abnormalities and does not impair the short and long-term survival of the patient. Together with the orthopedic abnormalities, if significant and left untreated, it may cause a decrease in the quality of life in the adolescent and adult patients.

Presentation

Prenatal Diagnosis and Management

Prenatal ultrasonography has played a major role in the identification of congenital genitourinary abnormalities. Fetal hydronephrosis can be diagnosed accurately in the second trimester and is present in approximately 1% of all pregnancies. However, the cause of the hydronephrosis cannot be accurately determined in all cases. Elder (1990) estimated that the accuracy of determining the cause of fetal hydronephrosis varies from 30% to 85%.

In particular, PBS occurs prenatally with findings similar to those of other causes of bladder outlet obstruction (Fig. 32.14), **as in posterior urethral valves or megacystis-megaureter syndrome** (Kramer, 1983). **Although an accurate diagnosis of PBS has been made as early as 11 to 14 weeks of gestation** (Shimizu et al., 1992; Yamamoto et al., 2001; Fig. 32.15), **the classic findings of hydroureteronephrosis, a distended bladder, and irregular abdominal circumference are not consistently seen at 30 weeks** (Bovicelli et al., 1980; Christopher et al., 1982; Okulski, 1977; Shih et al., 1982). Early fetal ascites has been suggested to correlate with PBS (Scarbrough et al., 1988). The majority of patients with PBS do not have demonstrable urinary obstruction, and the degree of hydroureteronephrosis does not correlate with the postnatal renal function (Gadziala et al., 1982).

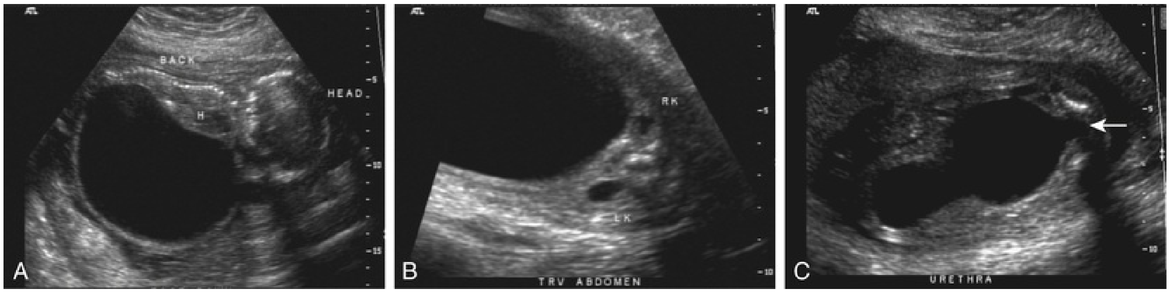

FIG. 32.14 Prenatal sonogram of a fetus with prune-belly syndrome. (A) Massively dilated bladder that fills most of the abdominal cavity. Note the lack of amniotic fluid. (B) The cephalic portion of the bladder reaching the level of both kidneys with hydronephrosis and renal parenchyma noted. (C) A dilated bladder with a urachal diverticulum *(arrow)* and an elongated and dilated posterior urethra. (Courtesy C. Peters.)

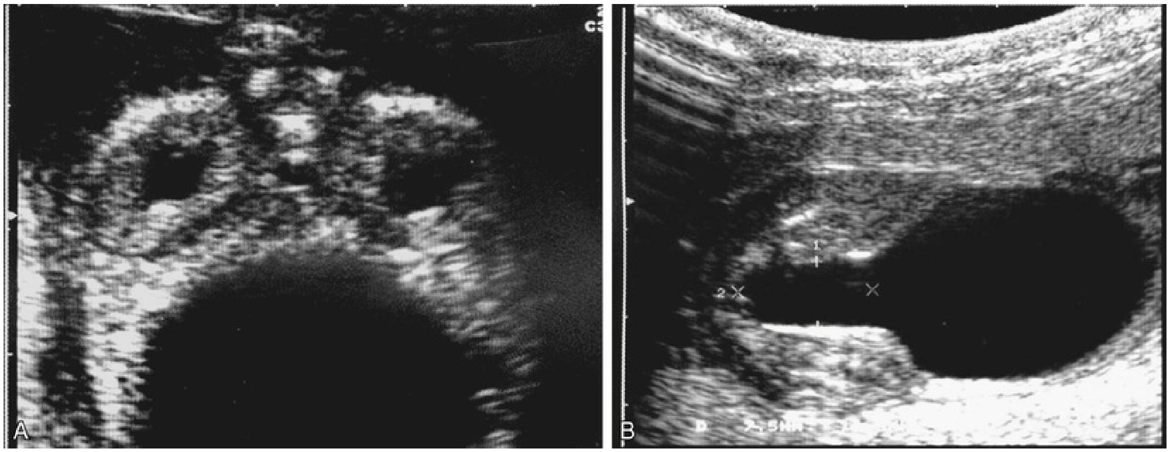

FIG. 32.15 (A) Fetus with prune-belly syndrome demonstrating distended bladder with hydronephrotic echogenic kidneys. (B) Distended bladder with dilated prostatic urethra indicative of outlet obstruction from urethral atresia. (Courtesy E. Ruiz.)

Whereas some have recommended in utero intervention for relief of urinary tract dilation and oligohydramnios (Estes and Harrison, 1993; Gadziala et al., 1982; Glazer et al., 1982; Leeners et al., 2000; Nakayama et al., 1984; Scarborough et al., 1988), others have recommended termination of pregnancy (Pescia et al., 1982). **Nevertheless, it is difficult to justify the advocacy of pregnancy termination in light of our inability to diagnose precisely the cause of prenatal hydronephrosis and inability to predict postnatal renal function on the basis of the degree of urinary tract dilation, except in rare cases of early and severe oligohydramnios.** Prenatal intervention has been applied to PBS with no proven benefit in terms of postnatal renal function (Biard et al., 2005; Blaicher et al., 2005; Elder et al., 1987; Freedman et al., 1999; Sholder et al., 1988). The only circumstances in which prenatal intervention may be justified are the rare situations of urethral atresia with progressive oligohydramnios (Perez-Brayfield et al., 2001; Reinberg et al., 1993; Steinhardt et al., 1990) or cases in which decompression of the urinary tract is necessary to prevent dystocia (Gadziala et al., 1982).

Neonatal Presentation

The appearance of the abdominal wall immediately suggests the diagnosis of PBS (see Fig. 32.7), whether or not the diagnosis was suspected prenatally. Other associated abnormalities such as cardiac or pulmonary should take precedence over the urinary tract because, in the absence of true bladder outlet obstruction, as seen with urethral atresia, the hydroureteronephrosis is not life threatening.

Spectrum of Disease

With the number of variable anomalies present in PBS, it is understandable that there is a wide spectrum of clinical presentations. The three major categories of presentation in the neonatal period were described by Woodard (1985; Table 32.2).

TABLE 32.2

Spectrum of Prune-Belly Syndrome

CATEGORY	CHARACTERISTICS
I	Renal dysplasia
	Oligohydramnios
	Pulmonary hypoplasia
	Potter features
	Urethral atresia
II	Full triad features
	Minimal or unilateral renal dysplasia
	No pulmonary hypoplasia
	May progress to renal failure
III	Incomplete or mild triad features
	Mild to moderate uropathy
	No renal dysplasia
	Stable renal function
	No pulmonary hypoplasia

Category I

Category I consists of neonates who have experienced marked oligohydramnios as a result of renal dysplasia or severe bladder outlet obstruction with resultant pulmonary hypoplasia and skeletal abnormalities. Most infants with urethral atresia fall in this category. The exceptions to this are patients with urethral atresia and a patent urachus (Rogers and Ostrow, 1973). Those in this category who are not stillborn commonly succumb within a few days of life to pulmonary hypoplasia or later to renal failure. Approximately 20% of newborns with PBS die in the perinatal period

(Burbige et al., 1987; Fallat et al., 1989; Woodard and Parrott, 1978b). It would be unusual for any urologic intervention in this category of patients to alter the course of events. Simple catheter drainage is all that is justifiable.

Category II

Category II patients demonstrate the full spectrum of the disorder with moderate or unilateral renal insufficiency and moderate to severe hydroureteronephrosis. Pulmonary hypoplasia is not a prominent feature of this group of patients. The clinical course is that of stabilization of renal function at or somewhat below normal or progressive azotemia. The presence of significant hydroureteronephrosis, vesicoureteral reflux, and postvoid residual, causing urinary tract infection, is associated with recurrent pyelonephritis, which further compromises renal function. It is in this group of patients that significant controversy over management exists (Randolph, 1977; Waldbaum and Marshall, 1970; Woodard and Parrott, 1978b).

Category III

Category III consists of patients with mild features of the triad or incomplete forms of PBS. This category comprises the majority of patients with PBS in whom hydroureteronephrosis is present to some degree but renal function is well maintained (Woodard, 1998; Woodhouse et al., 1982). **There is no evidence of pulmonary insufficiency.** There is little controversy that urologic intervention in the group is reserved for patients who demonstrate repeated urinary tract infections, probably related to urinary stasis or vesicoureteral reflux, or development of upper tract deterioration (Woodard and Smith, 1998). As previously noted, there is poor correlation between the extent of abdominal wall deficit and the degree of hydronephrosis or renal dysplasia, or both. This is also apparent in other variants of the syndrome. Some children have markedly dilated urinary tracts with minimal or no dysplasia and therefore normal renal function. Therefore the appearance of the abdominal wall or the degree of hydronephrosis may have little bearing on the long-term prognosis of children with PBS.

Incomplete Syndrome

Patients with incomplete syndrome are males who may not have all the features of the triad syndrome but share other features. Some of them, also called *pseudo* *prune* patients, have unilateral abdominal wall deficiency and unilateral undescended testis (Grover et al., 2017). **Most typically, these incomplete forms of the syndrome lack the typical abdominal wall features but have the common uropathy and cryptorchidism. Many of these patients may experience renal failure and therefore require close observation, monitoring, and selective intervention.** Bellah reported a relatively high (8/15) tendency to progressive renal failure in his population of pseudo prune patients. This may be partially attributed to a delay in diagnosis in the absence of the obvious abdominal musculature deficiency and therefore a tendency to experience recurring urinary tract infections (Bellah et al., 1996).

Adult Presentation

Patients with incomplete forms of PBS and specifically those who lack the abdominal wall features may seek medical assistance as late as adulthood with symptoms of renal failure and hypertension (Kerbl and Pauer, 1993; Lee, 1977). Although there have been isolated reports of adults with no history of urinary tract infections, most who present in adulthood eventually develop urinary tract infections from the chronic urinary stasis associated with the syndrome (Culp and Flocks, 1954).

Female Syndrome

Five percent of patients with PBS are female, most of whom have abdominal wall deficiency and an abnormal urinary tract (Reinberg et al., 1991b). Rabinowitz and Schillinger (1977) reported female patients with the typical abdominal wall deficit and a normal urinary tract. In the series of Reinberg et al. (1991b), bladder outlet obstruction was commonly seen along with a 40% occurrence of anorectal anomalies similar to the statistics for the male; 40% did not survive the newborn period.

Evaluation and Management

Initial Management

The initial evaluation of the newborn with PBS requires a team consisting of a neonatologist, a nephrologist, and a urologist. Other specialists, particularly a cardiologist, may be indicated. Early orthopedic evaluation is also warranted. The major initial concern is that of management of cardiac and respiratory issues. An immediate chest radiograph is necessary to exclude commonly associated pulmonary abnormalities such as pneumothorax, pneumomediastinum, and pulmonary hypoplasia, which is commonly a result of oligohydramnios (Perlman and Levin, 1974). Early urologic intervention is indicated only for neonates with evidence of bladder outlet obstruction, in whom a percutaneous suprapubic tube can be inserted in the neonatal intensive care unit.

Initial evaluation of renal function and the urinary tract status is important but must be tempered by transitional neonatal physiology. Although an initial creatinine level is important in establishing a baseline, it may be more reflective of the mother's renal function, and therefore the trend in creatinine levels over the course of the early postnatal days or weeks is much more predictive of long-term renal function.

Serum creatinine, blood urea nitrogen (BUN), and electrolytes are necessary to assess for the potential systemic acidosis and electrolyte imbalances that may be seen in renal insufficiency. It has been shown in multiple reports that a baseline creatinine level of less than 0.7 mg/dL is predictive of adequate renal function through childhood in the absence of repeated insults from pyelonephritis (Geary et al., 1986; Noh et al., 1999; Reinberg et al., 1991a).

Early renal and bladder ultrasonography, once the newborn is stabilized, is necessary to assess the renal parenchyma for its thickness, density, and presence or absence of cortical cysts and degree of urinary tract dilation (see Fig. 32.1).

Avoidance of urinary tract infection is essential because of urinary stasis and often compromised baseline renal function. Circumcision is advisable in the absence of a structural penile abnormality to reduce the risk of infant urinary tract infections. Similarly, prophylactic antibiotic therapy is recommended, especially before urinary tract instrumentation, including

the initial voiding cystourethrogram (VCUG). Although instrumentation without a defined purpose that may alter management should be avoided, a VCUG to assess the bladder outlet and bladder emptying ability, especially in the presence of renal insufficiency, is warranted (Woodard and Smith, 1998). The VCUG is necessary in neonates with renal insufficiency to rule out bladder outlet obstruction as the cause versus urinary stagnation. In up to 70% of children with PBS, vesicoureteral reflux is diagnosed (Berdon et al., 1977; Fallat et al., 1989). A recent study reported the usefulness of magnetic resonance urography (MRU) in revealing significant anatomic and functional findings that were not readily apparent when using standard imaging for children with PBS, such as calyceal diverticula, abnormal renal pelvic anatomy, and particularly renal dysplasia, which is poorly characterized in the PBS population outside of renal biopsy studies (Garcia-Roig et al., 2016). Therefore MRU may provide a more detailed assessment than isolated kidney and bladder ultrasonography, excretory urography, or renal nuclear scan techniques. Disadvantages of MRU are the need for gadolinium (with contrast-associated risks, including the rare occurrence of nephrogenic systemic fibrosis), its high cost and availability, and the need for sedation (Garcia-Roig et al., 2016).

Any instrumentation should be carried out with strict attention to sterile technique to reduce the risk of inoculation of a static urinary system. An early VCUG is not necessary in the presence of normal renal function and evidence of adequate bladder drainage per urethra or a patent urachus.

Key Points: Initial Management

- A team consisting of neonatology, nephrology, urology, and other specialties such as cardiology is necessary.
- A VCUG is indicated in the neonatal period if there is renal insufficiency or evidence of bladder outlet obstruction and only after antibiotic prophylaxis.
- A chest radiograph to evaluate for pneumothorax, pneumomediastinum, and pulmonary hypoplasia is necessary.
- Baseline assessment of renal function should include renal and bladder ultrasonography, BUN, creatinine, and electrolytes.
- Circumcision is advisable in the absence of a structural penile abnormality.
- Early intervention is indicated for evidence of bladder outlet obstruction and

preferably with a percutaneous suprapubic tube.

As noted, neonates can be categorized on the basis of their spectrum of disease (see Table 32.1). *Category I:* There is little disagreement on the management of category I patients with PBS because there is no evidence that anything beyond supportive care is justifiable. In particular, intervention in the urinary tract is not indicated beyond simple bladder drainage because the fate of these patients usually cannot be altered (Woodard and Smith, 1998).

Category III: At the other end of the spectrum, category III patients rarely require early urologic intervention for the urinary tract because they are in a balanced state of hydronephrosis with good, if not normal, renal function. Children in this category require regular monitoring of urinary tract dilation (ultrasonography) and renal function (serum creatinine), as well as urinary tract infection. However, their cryptorchidism requires correction during the first year of life. Some of these patients have persistent vesicoureteral reflux that may require surgical treatment on mid- to long-term follow-up, if symptomatic. Others will also benefit from abdominoplasty (▶Video 32.1) because they may have significant flaccidity that persists or worsens during childhood.

Category II: These patients require individualized evaluation and management on the basis of the fact that within this category there are variable degrees of severity of each facet of PBS. There is, however, much controversy over their management. Evaluation of renal function or renal drainage, or both, is required in those with renal insufficiency. Excretory urography, although providing dramatic images of the urinary tract (see Fig. 32.3), does not provide sufficient information on comparative function. Renal parenchymal function is best assessed by a technetium-99m (^{99m}Tc)-dimercaptosuccinic acid (DMSA) renal scan at 4 to 6 weeks of age to prevent difficulties in interpretation related to transitional neonatal physiology. Renal outflow obstruction is best assessed by ^{99m}Tc-mercaptoacetyltriglycine (MAG3), which also provides an assessment of comparative renal function with massive hydronephrosis and resultant stasis. In the presence of poor renal function, assessment of renal outflow obstruction by nuclear scan techniques may be limited; therefore selective use of the Whitaker antegrade perfusion test may be helpful.

Aggressive surgical intervention was initially derived from early observations of the unfavorable mid- and long-term prognosis for category II infants as a group. Compilation of the cases reported in the literature between 1950 and 1970 by Waldbaum and Marshall (1970) revealed that 86% of the 56 accurately traceable patients had died, with or without surgical intervention. The obvious implication was that a more aggressive approach was necessary to improve the fate of the infant with PBS. With the recognition that infection and progressive renal insufficiency are the factors that most often pose the greatest threat to quality of life and survival, surgical reconstruction to normalize the anatomy and function of the genitourinary tract was advocated. Early reconstruction of the urinary system to reduce stasis and eliminate reflux or obstruction has included ureteral shortening, infolding, and vesicoureteral reimplantation as well as reduction cystoplasty. Although rarely, eventual dysplastic or hydronephrotic kidneys with severely reduced function may require removal if symptomatic. Reconstruction is best delayed until the child is at least 3 months of age to allow for pulmonary maturation. This approach has been successful in achieving anatomic and functional improvement as evidenced by stable radiographic studies, stable creatinine values, and a reduced occurrence of infection (Jeffs et al., 1977; Randolph et al., 1981b; Waldbaum and Marshall, 1970; Woodard and Parrott, 1978b). Early urinary tract reconstruction can be done comprehensively with orchiopexy, abdominoplasty, and circumcision without increasing the morbidity of the procedure. In a report of comprehensive reconstructive experience, 35 patients who have undergone urinary tract reconstruction have maintained a normal creatinine level, whereas 5 demonstrated moderate to severe renal insufficiency, and 3 required renal transplantation in a follow-up ranging from 15 months to 26 years (Lopes et al., 2015).

An alternative approach of limited surgical intervention has also been applied. Proponents advocate close surveillance with medical management of bacteriuria and surgical intervention only in patients with proven obstruction or intractable infection. Opinions vary about the management of vesicoureteral reflux in the PBS population. There is no reason to believe that reflux in this population is any less important, and correction of high-grade reflux seems prudent. Success with minimal surgical intervention has been reported (Duckett et al., 1980; McMullin et al., 1988; Tank and McCoy, 1983; Woodhouse et al., 1979). On the other hand, Woodhouse et al. (1979) reviewed a series of patients with PBS managed conservatively. Of these 11 patients, who were monitored from infancy, 9 remained well except for a few urinary tract infections for periods of up to 24 years. They were said to have normal voiding patterns and normal renal function. Certainly, patients in category III are candidates for this type of management.

The paucity of long-term data for category II patients, the probable variation in assignment of disease severity in treatment groups, and the variable natural history of the disease make comparisons of these retrospective studies difficult. **Spontaneous improvement in ureteral appearance and function may occur with normal growth and elongation of the ureters** (Duckett et al., 1980). **Also, some patients with gross abnormalities of the urinary collecting system have survived decades without medical attention** (Asplund and Laska, 1975; Lee, 1977; Texter and Koontz, 1980). **Yet progressive uropathy is also well known to occur, and many patients with PBS ultimately require renal transplantation** (Reinberg et al., 1989). Controversy will persist over category II patients until accurate application of a medical or surgical approach is possible on the basis of distinct clinical features. Lopes et al. (2015) emphasize the individualization of care in their 27-year experience with 46 patients.

Surgical Management of the Patient With Prune-Belly Syndrome

Surgical management of children with PBS can be divided into three categories: urinary tract procedures, orchiopexy, and abdominal wall reconstruction.

Urinary Tract

Urinary tract reconstruction is generally reserved for children with progressive or severe hydroureteronephrosis, high-grade vesicoureteral reflux, recurrent upper tract infections, true obstructive uropathy, and progressive renal failure. Temporary urinary diversion also has a role in the very young or the very ill child.

Urinary Diversion

Supravesical Urinary Diversion.

In some patients the occurrence of repeated upper tract infections or deterioration of renal function dictates the need for temporary urinary diversion. Although cutaneous vesicostomy usually provides adequate upper tract drainage and decompression, in rare instances more proximal diversion is indicated because of ureteropelvic or ureterovesical junction obstruction. In these settings, a cutaneous pyelostomy or a distal ureterostomy, respectively, are advocated rather than a proximal ureterostomy because they avoid sacrificing a normal proximal ureter that may be useful in later reconstruction.

Cutaneous Vesicostomy.

Urinary diversion may be necessary as a temporary measure in children with acute renal failure, urinary sepsis, or bladder outlet obstruction from urethral atresia with limited patency of the urachus (Fig. 32.16) (Joseph, 1999; Teramoto et al., 1981). **When temporary urinary diversion is indicated, a cutaneous vesicostomy is the procedure of choice. This is best done by the Blocksom technique as described by Duckett (1974) and Duckett et al. (1980).** If there is a large urachal diverticulum, it can be excised at that time. It is advisable to create a larger-than-normal stoma in the patient with PBS because stenosis is common, probably because of the decreased intra-abdominal pressure (Snow and Duckett, 1987).

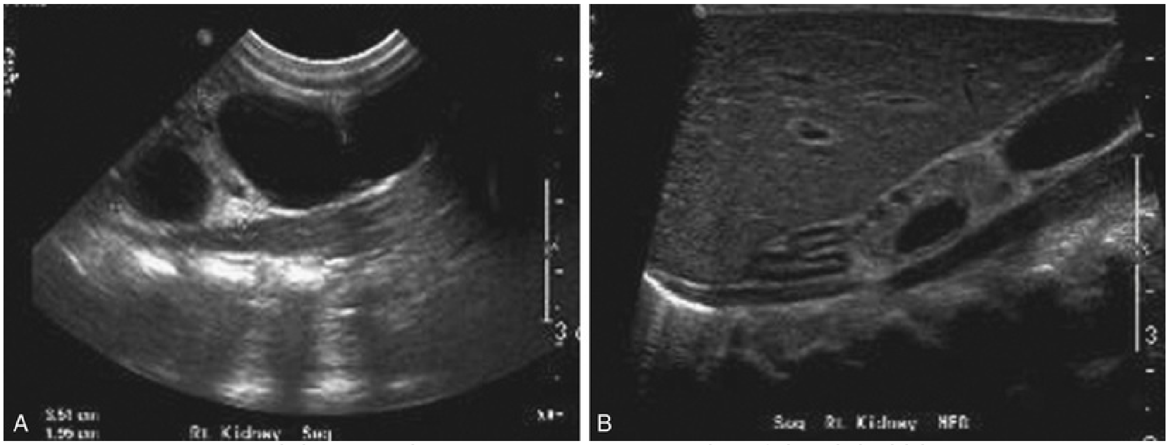

FIG. 32.16 (A) Prevesicostomy ultrasonography of the right kidney demonstrating massive hydronephrosis with echogenic parenchyma. (B) Postvesicostomy ultrasonography demonstrating a decompressed kidney with echogenic parenchyma and cortical cysts. (Courtesy C. Peters.)

Upper Urinary Tract Reconstruction

Ureteroplasty and Ureterocystoneostomy.

Ureteral remodeling remains controversial. It is best undertaken in children who demonstrated repeated nonsuppressible upper urinary tract infections or those with progressive anatomic or functional upper tract deterioration resulting from ureteral dilatation and tortuosity, frequently associated with vesicoureteral reflux (Fig. 32.17). **The goal of remodeling and reimplantation is to reduce urinary stasis and correct massive reflux.** The key to success relies on meticulous surgical technique and preservation of the upper few centimeters of proximal ureter, which are often less dilated, for reconstruction. Even then, tailoring or infolding of these segments may be necessary for adequate reimplantation into the abnormal bladder. This step can be difficult, in that the creation of a submucosal tunnel in the abnormal bladder for these ureters can be challenging (Woodard and Trulock, 1986).

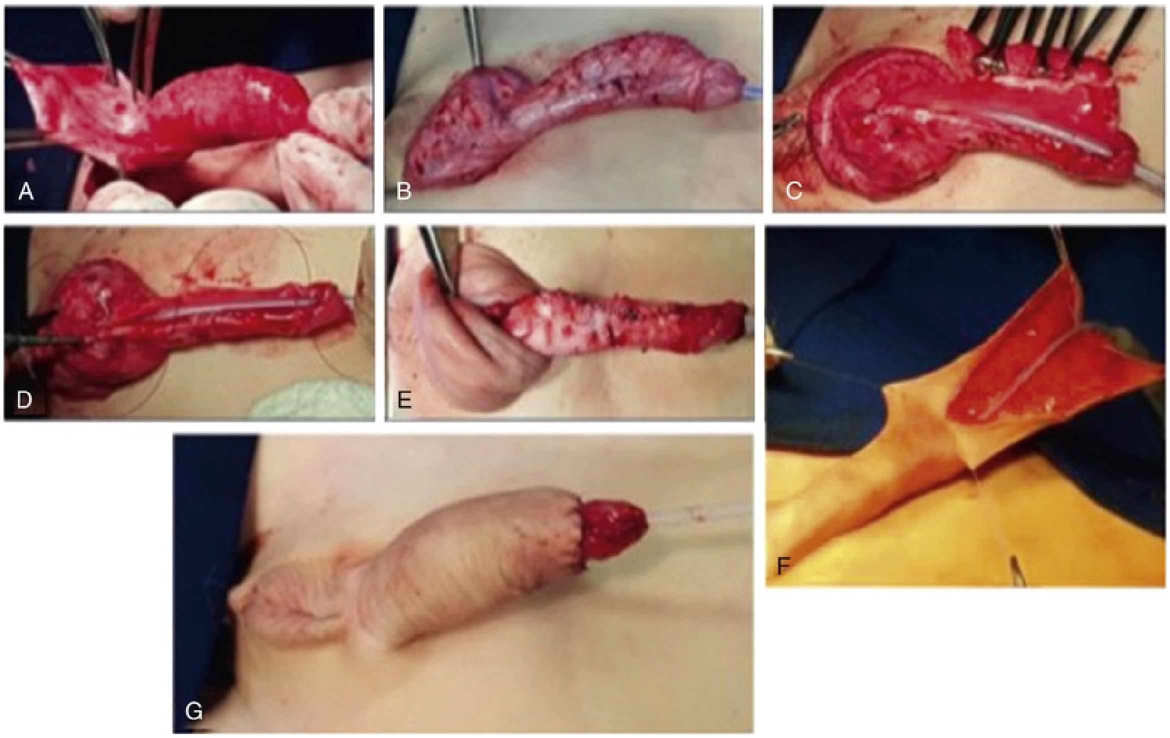

FIG. 32.17 Surgical correction of megalourethra in a patient with the prune-belly syndrome: (A) Penile deglovement. (B) Exposure of the scaphoid megalourethra. (C and D) Tailoring of the dilated urethral segment. (E) Completed urethroplasty. (F) Presentation of excessive preputial skin. (G) Completed procedure after urethroplasty and circumcision (note empty scrotum).

Pyeloplasty.

In cases with associated secondary ureteropelvic junction obstruction, proximal ureterolysis without compromising ureteral vascularization may decompress the renal pelvis. In those with true mechanical obstruction, a nondismembered ureteropyelostomy between the dilated pelvis and a normal upper ureteral segment may normalize urinary drainage.

Woodard et al. have demonstrated excellent success in this population when these procedures were performed in the neonatal period or in the older child

(Woodard and Parrott, 1978b; Woodard and Zucker, 1999). However, they no longer recommend such extensive reconstructive surgery before the age of 3 to 6 months. Fallat et al. (1989) as well as Lopes et al. (2015) have reported excellent results of extensive comprehensive surgery, including the reconstruction of the upper and lower urinary tracts, abdominoplasty, and orchiopexy in large groups of patients, with experiences ranging from 17 to 27 years that showed functional stabilization of the urinary tract in up to 90% of the children.

Lower Urinary Tract Reconstruction

Reduction Cystoplasty.

In many patients with PBS, poor bladder contractibility leads to incomplete and infrequent vesical emptying, further increasing urinary stasis or vesicoureteral reflux. This leads to the concept of reducing the size of the bladder and remodeling it into a more spheric shape to better direct the contractible forces (Perlmutter, 1976). A variety of approaches have been proposed, from simple excision of the urachal diverticulum to the excision of redundant mucosa with the creation of overlapping between flaps to improve contractibility (Williams and Parker, 1974; Woodard and Trulock, 1986). Over time, however, high bladder capacity and residual volumes seem to recur (Bukowski and Perlmutter, 1994). It seems therefore that reduction cystoplasty would be justified only to remove the larger urachal diverticulum or as part of a more extensive urinary tract reconstruction. In some patients, intermittent catheterization through the urethra or through an appendicovesicostomy channel is likely to afford better long-term bladder emptying with reduction of residual urinary volumes until the patient is able to achieve better voiding pressures with age or as a result of abdominoplasty (Joseph, 1999).

Internal Urethrotomy.

The normal resistance of the urinary sphincter has been implicated in “unbalanced” urethrovesical function, contributing to large postvoid residuals. Snyder and Cukier proposed lowering urethral resistance by internal urethrotomy to improve bladder emptying (Cukier, 1977; Snyder et al., 1976). In patients studied by urodynamic flow rate profilometry, improved flow rates with reduced residual urine and improvement in the radiographic appearance of the upper tracts were found (Snyder et al., 1976; Woodhouse et al., 1979). Internal urethrotomy has been considered in PBS children with high postvoid residuals, increasing hydroureteronephrosis, or vesicoureteral reflux with recurrent upper tract infections but sustained long-term success has not been demonstrated. Williams (1979) advocated using an Otis urethrotome achieving a No. 24- to 30-Fr caliber with one or two incisions made anteriorly or anterolaterally, whereas Smith and Woodard (2002) recommended direct visual urethrotomy at the distal end of the prostatic urethra. Interestingly, internal urethrotomy did not result in incontinence in this population. Despite these early reports, no further experience with urethrotomy has been described. It is difficult to imagine this procedure being performed in infants and small children currently.

Anterior Urethral Dilation or Reconstruction.

Urethral maldevelopment may be present as urethral atresia or hypoplasia (see Fig. 32.4). Patients with this abnormality may survive without any intervention but frequently require some form of treatment to improve bladder emptying. Passerini-Glazel et al. (1988) reported on progressive gentle urethral dilation with good success. This technique may be used in situ or through and through in cases in which a vesicostomy has been performed (Fig. 32.18). As reported by Reinberg et al. (1993), however, urethral dilation is not uniformly successful. More recently, Kajbafzadeh et al. (2010) reported significant improvement of the urethral caliber after one to three sessions of hydrodistention in patients with urethral hypoplasia. Although a reasonable alternative in difficult cases, there are no reports of formal urethroplasties with skin or mucosal grafts in patients with PBS.

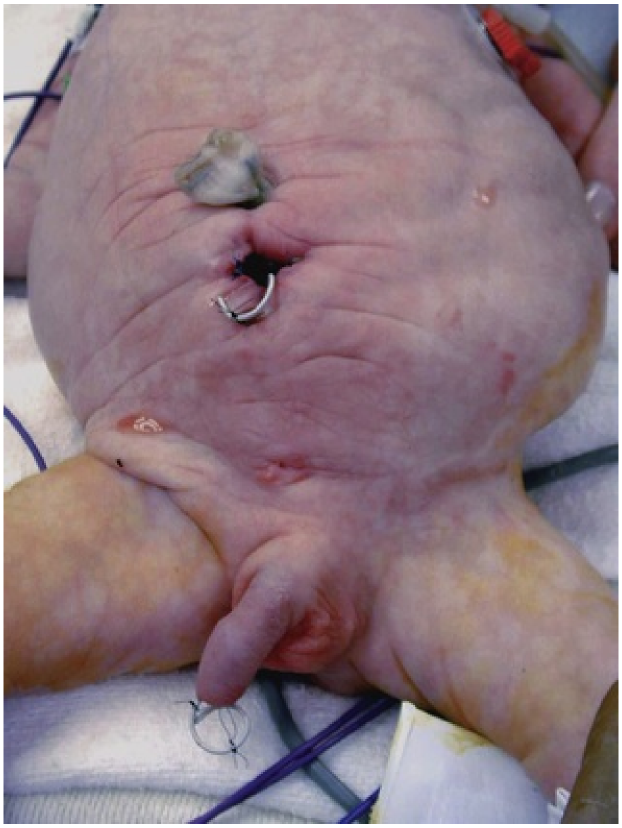

FIG. 32.18 Prune-belly syndrome patient with urethral atresia. Note vesicostomy and double-J stent through the urethra for progressive urethral dilation.

As noted previously, megalourethra in PBS is common, either in the fusiform or scaphoid types (Appel et al., 1986). This is best approached with a circumferential subcoronal incision and penile degloving (Fig. 32.19). The redundant urethra can be excised or infolded to provide support and reconstructed over an appropriately sized catheter. Alternatively, some of the urethra can be used to reinforce the urethroplasty because in either form of megalourethra the spongiosum is deficient.

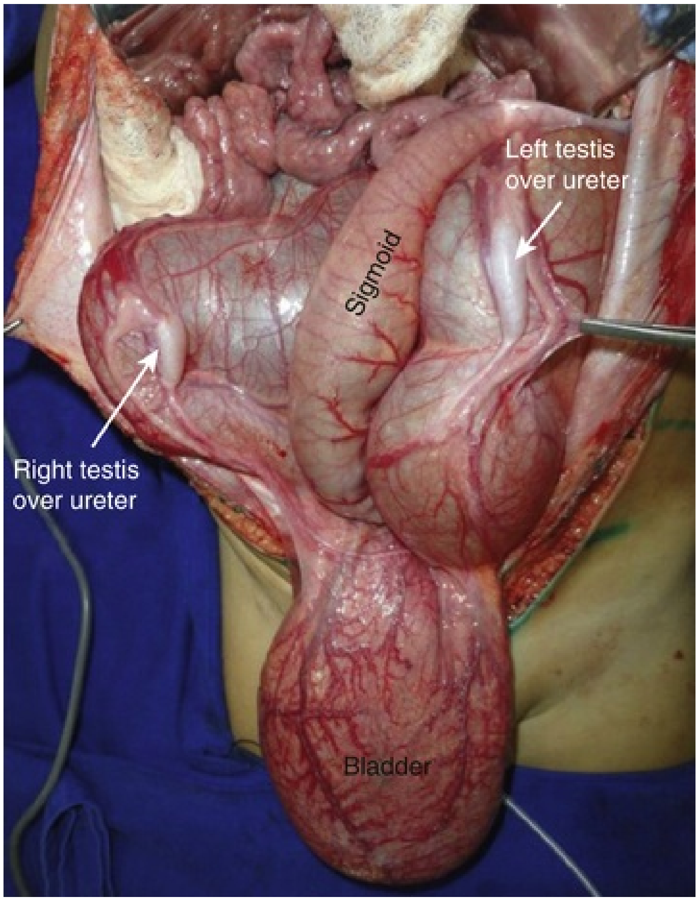

FIG. 32.19 Intra-abdominal testes *(arrows)* overlying massively dilated ureters.

Circumcision.

As in other boys who are at risk of developing recurrent urinary tract infection because of lower urinary tract abnormalities such as posterior urethral valves and vesicoureteral reflux, patients with PBS certainly benefit from circumcision as a means to decrease the incidence of recurring urinary tract infections. Lopes et al. (2015) incorporated circumcision in all their patients with PBS who were submitted to urinary tract reconstruction, orchidopexy, or abdominoplasty.

Testes: Orchidopexy

The timing of orchidopexy is dictated by our current understanding of the need for early treatment of the undescended testis in patients both with and without PBS along with the need of individual patients with PBS for either temporary or reconstructive surgery. Although the fertility potential of the patient with PBS is known to be compromised, germ cells are present in the testes of infants with PBS, and spermatozoa were found in the semen and post-ejaculatory urine samples of adult patients who underwent orchidopexy early in infancy (Dénes et al., 2017). In addition, the prognosis for normal hormonal function at puberty is excellent. These factors, along with the potential risk of testicular carcinoma (Massad et al., 1991; Uehling et al., 1984), would justify early orchidopexy. Because the testes are uniformly located in the abdomen, most commonly on a broad mesorchium overlying the iliac vessels (Coplen et al., 1996), standard inguinal approaches are not usually successful in achieving a satisfactory scrotal position. Four alternative approaches may be considered.

Transabdominal Orchidopexy.

Woodard, Parrott, and other researchers noted that if an orchidopexy is done in the neonatal period and up to 6 months of age by a transabdominal approach, adequate spermatic vessel mobilization can usually be achieved for scrotal placement (Fallat et al., 1989; Randolph et al., 1981a; Woodard and Parrott, 1978a, 1978b). **Transabdominal bilateral orchidopexy at about 6 months of age is currently considered the approach of choice** (Fig. 32.20). This approach is often used in conjunction with other abdominal surgeries, either a vesicostomy, urinary tract reconstruction, or abdominal wall reconstruction. In the absence of need for other abdominal surgeries, this can be accomplished laparoscopically (Philip et al., 2011).

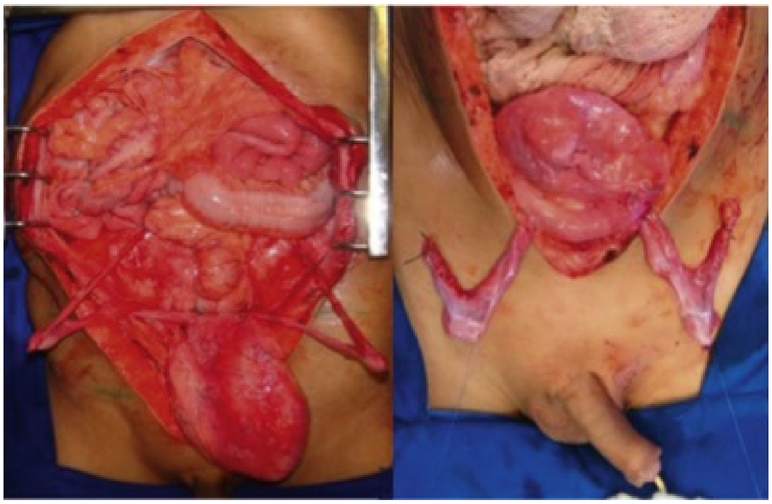

FIG. 32.20 Transabdominal orchidopexy with and without preservation of the vascular pedicle in patients with the prune belly syndrome.

Spermatic Vessel Ligation.

When successful transabdominal orchidopexy cannot be accomplished in the first few months of life, the other options that may be considered are (1) Fowler-Stephens orchidopexy (Boddy et al., 1991; Fowler and Stephens, 1959; Gibbons et al., 1979; Kirsch et al., 1998), **(2) staged Fowler-Stephens orchidopexy** (see Fig. 32.18) (Bloom, 1991; Caldamone and Amaral, 1994; Docimo, 1995; Ransley et al., 1984; Yu et al., 1995), and **(3) microvascular autotransplantation** (Boddy et al., 1991; MacMahon et al., 1976; Wacksman et al., 1980). A meta-analysis report by Docimo (1995) indicated comparative success rates of 67% and 77% for standard and staged Fowler-Stephens techniques, respectively.

Laparoscopic Orchidopexy.

In a multi-institutional report of laparoscopic orchidopexy, Baker et al. (2001) noted a success rate of 81% for a standard Fowler-Stephens approach compared with 90% for a staged approach. In a long-term follow-up report, Patil et al. (2004) reported a satisfactory outcome in PBS with a one- or two-stage Fowler-Stephens orchidopexy (Fig. 32.21). Some authors have recommended several technical adjustments during laparoscopic orchiopexy in children with PBS, particularly port placement because there is little resistance to cannula placement in these children (Saxena and Brinkmann, 2007).

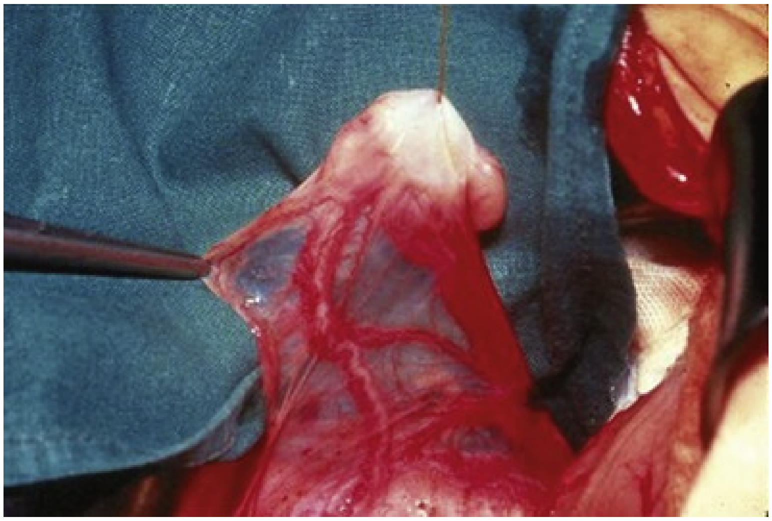

FIG. 32.21 Operative photograph showing increased vascularity along vas deferens 4 months after first-stage Fowler-Stephens orchidopexy.

Abdomen: Reconstruction of the Abdominal Wall

Indications.

Children with mild degrees of abdominal muscular deficiency may show improvement in the abdominal wall laxity as they mature. However, most others with moderate to severe degrees of abdominal wall laxity are left with a potentially physically and psychologically crippling defect (Ehrlich et al., 1986; Parrott and Woodard, 1992). An elasticized corset can improve the external appearance when the patients are fully clothed as well as improve the respiratory and gastrointestinal problems, even in the neonatal period (Satar et al., 2016). Nevertheless, these corsets may become inconvenient to use in the long term, particularly in regions with warm climate.

There is general agreement about the cosmetic benefit of abdominal wall reconstruction. However, whether it improves bladder, bowel, and pulmonary function is controversial (Smith et al., 1998; Woodard, 1998). Smith et al. demonstrated improved bladder emptying after abdominal wall reconstruction; nevertheless, some of their reconstructed patients underwent concomitant urinary tract remodeling as well. Potential effects include a more effective cough and improvement in defecation. The timing of abdominal wall reconstruction should be dictated by the need for other surgical interventions, particularly if upper urinary tract remodeling is necessary. If upper tract remodeling is not anticipated, the abdominal wall can be addressed at any time and has been done as young as 6 months of age along with transabdominal orchidopexy (Smith and Woodard, 2002). However, if the procedure is done in infancy, the infant may have to be placed on a respirator postoperatively for a period of time.

Techniques

Randolph Technique.

Randolph et al. (1981a), first popularized a technique for abdominal wall reconstruction based on electromyographic mapping, which indicated that the most severely affected area of the abdomen is the infraumbilical regions, whereas the lateral and supraumbilical regions are generally least affected. This technique makes a transverse incision from the 12th rib to the pubic symphysis to the opposite 12th rib with a full-thickness removal of the skin, lower abdominal musculature, and peritoneum. The healthy fascia is then approximated to the anterior iliac spines, pubic tubercle, and inferior fascia.

Although this technique is successful in establishing a waistline, lateral abdominal bulging often persists. Of the 16 patients reported, 9 had excellent cosmetic results and there was some residual protuberance in 7 (Fallat et al., 1989).

Ehrlich Technique.

The technique described by Ehrlich used a vertical midline incision and allows preservation of the umbilicus on a vascular pedicle from the inferior epigastric artery (Ehrlich et al., 1986; Ehrlich and Lesavoy, 1993). The skin and subcutaneous tissues are elevated off the muscle and fascial layers, and an overlapping, vest-over-pants advancement of each side to the contralateral flank is performed, preserving the less affected lateral muscles and fascia. Excellent long-term follow-up of this technique has been reported (Lesavoy et al., 2012).

Monfort Technique.

Monfort described a technique that is vertically oriented similar to that of Ehrlich's approach; however, an elliptically oriented incision is used to isolate the redundant skin (Monfort et al., 1991). The incision extends from the tip of the xyphoid to the pubis. A second incision is made around the umbilicus to preserve it in situ. The skin and subcutaneous tissue are dissected off the attenuated fascia and muscle with the dissection extending laterally to the anterior axillary line. Vertical fascial incisions are made lateral to the superior epigastric arteries, leaving a central fascial bridge. If intra-abdominal surgery is necessary, excellent exposure to the urinary tract or abdominal testes is afforded through these lateral fascial incisions. After urinary reconstruction and/or orchidopexy, the lateral fascial is then advanced over the central fascial bridge from both sides, alleviating the redundancy and increasing the thickness of the abdominal wall (Fig. 32.22). Recently incorporated modifications, such as the use of diagnostic laparoscopy to define the topography of the abdominal wall defect, initial midline rather than elliptical skin incision to defer retailoring of the skin coverage until the final step of the procedure, varying the width of the central plate to correct side-to-side asymmetry in redundancy, plication of the central plate to reduce vertical redundancy and allow reposition of the umbilicus, and plication of focal areas of fascial weakness in the flank region, have improved the results of this abdominoplasty technique (Smith et al., 2017). A modification of the Monfort technique uses laparoscopy to protect the abdominal contents (Franco, 2005).

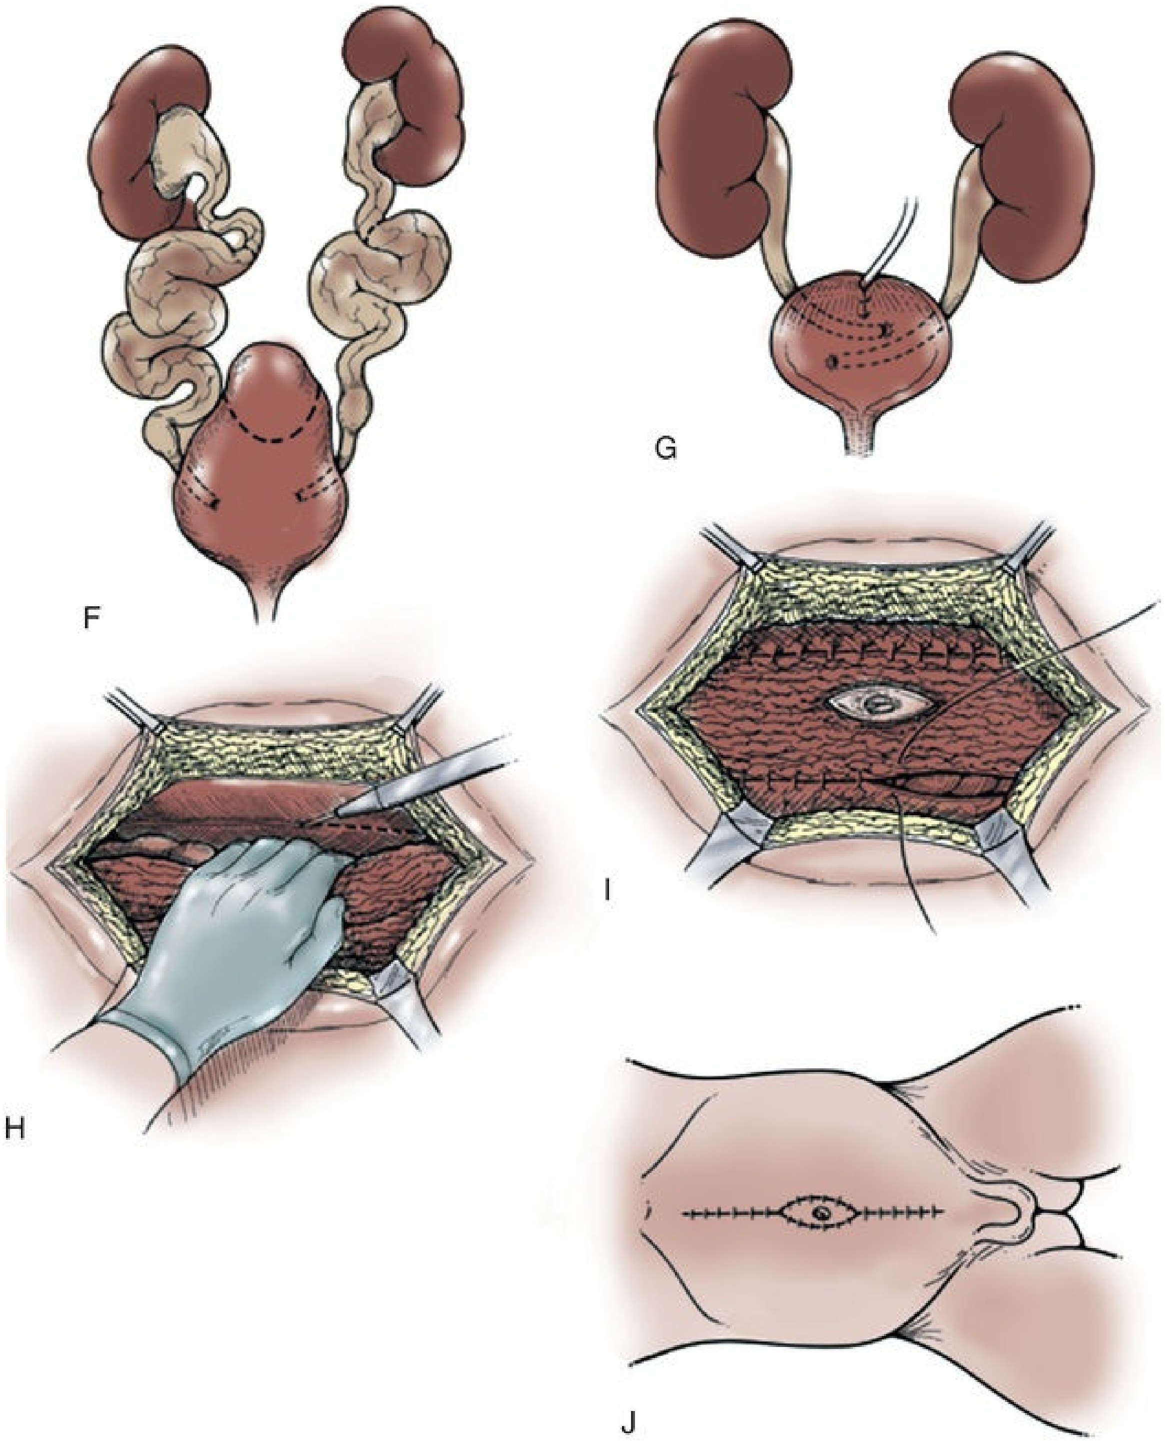

FIG. 32.22 Surgical technique for Monfort abdominoplasty and concomitant reconstruction of prune-belly uropathy. (A) Delineation of redundancy by tenting up abdominal wall. (B) Skin incisions are outlined with a separate circumscribing incision to isolate the umbilicus. (C) Skin (epidermis and dermis only) is excised with electrocautery. (D) Abdominal wall central plate is incised at the lateral border of the rectus muscle on either side, from the superior epigastric to the inferior epigastric vessels, creating a central musculofascial plate. (E) Adequate exposure is provided

for concomitant transperitoneal genitourinary procedures. *B,* Bladder; *T,* testis; *U,* ureter.(F) Only the more normal proximal ureter is preserved for vesicoureteral reimplantation, and the urachal diverticulum is excised. (G) Transtrigonal ureteral reimplantation is performed with or without ureteral tapering as needed. The bladder is closed in two layers, and ureteral stents (not shown) and a cystostomy tube are used. (H) Completion of abdominoplasty by scoring of the parietal peritoneum overlying the lateral abdominal wall musculature with electrocautery. (I) The edges of the central plate are sutured to the lateral abdominal wall musculature along the scored line. (J) Lateral flaps are brought together in the midline, with closed suction drains placed between the lateral flaps and the central plate. Skin is brought together in the midline, enveloping the previously isolated umbilicus. (From Woodard JR, Perez LM: Prune-belly syndrome. In Marshall FF, ed: *Operative urology,* Philadelphia, 1996, Saunders.)

Dénes Technique.

Another modification of the Ehrlich and Monfort techniques was reported in which, after the fusiform longitudinal resection of the mid-abdominal skin and subcutaneous tissue with preservation of the musculo-aponeurotic fascia and umbilicus, one elliptical xyphopubic incision is made in the more flaccid side of the abdominal fascia, producing one wide and one narrow fascial flap, with the umbilicus kept intact in the wide flap. Closure is made by suturing the wide flap laterally to the inner side of the narrow flap, followed by vest-over-pants suture of this flap over the wide, now “inner” flap, with a buttonhole exposing the umbilicus, which is then fixed in place. After slight undermining of both skin edges, they are approximated and sutured with incorporation of the umbilicus (Dénes et al., 2014) (Fig. 32.23). Abdominal appearance and tonus were improved in 90% of the children after the primary surgery and 100% after reoperation (Lopes et al., 2015) (Fig. 32.24).

Abdominoplasty closure: (I through J) suture of broad flap to inner side of narrow flap; (K through O) Pants-over-vest fixation of narrow flap over the broad flap (now inner flap), with a buttonhole for umbilicus. (P) Final aspect after approximation of subcutaneous and skin.

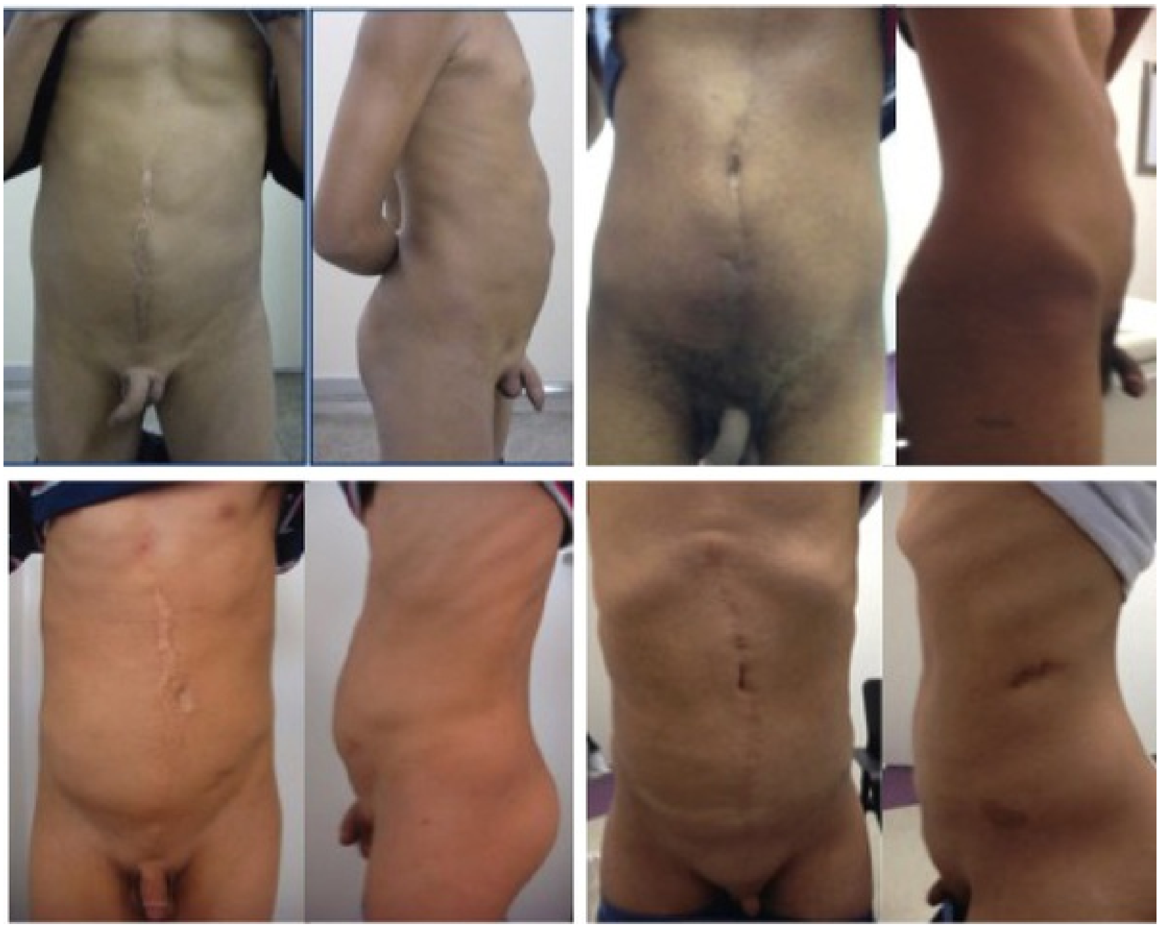

FIG. 32.24 Postoperative front and lateral images of patients with prune-belly syndrome submitted to abdominoplasty with the Dénes technique.

Furness Technique.

Furness et al. (1998) described a modified midline approach with less abdominal wall dissection that avoids entering the peritoneum, which is useful if an intra-abdominal surgery is not planned. A modification of the Monfort technique uses laparoscopy to protect the abdominal contents (Franco, 2005).

Key Points: Surgical Reconstruction

- Upper urinary tract reconstruction is controversial but clearly indicated for evidence of declining renal function in the presence of recurrent upper tract infections or progression of the hydroureteronephrosis.
- Orchidopexy is best performed early in life because this affords the most

likely prospect of a successful single-stage procedure, as well as the perspective of preservation of germ cells.

- Abdominal wall reconstruction, besides the obvious cosmetic and psychosocial benefits, has demonstrated improved bladder emptying, a more effective cough, and improved defecation.
- Comprehensive surgery that includes the all the above mentioned points, as well as circumcision, is feasible in most patients.

Long-Term Outlook

Quality of Life

The overall outlook for the patient with PBS for survival and for quality of life has improved considerably, largely through advances in medical, surgical, and urodynamic management. However, despite these advances in care of children with PBS, there continues to be a high perinatal mortality rate in patients of group I, largely because of associated prematurity, renal dysplasia, and pulmonary hypoplasia (Routh, 2010).

PBS profoundly affects health-related quality of life in affected children as well as in their caregivers. The patients have compromised physical, emotional, social, and school functioning, and the caregivers report an overall lower quality of life because of the burdens that families with chronically ill children often face (Arlen et al., 2016). Another study demonstrated that surviving individuals with PBS had a significantly high incidence of orthopedic, gastrointestinal, and cardiopulmonary conditions that negatively affected their quality of life, whereas treatment of these non-GU conditions improves their lives.

These studies stress the fact that, as primarily responsible for the overall health of these medically complex patients, the pediatric urologist must be aware and prepared not only to treat the late genitourinary complications of PBS but also to evaluate and diagnose the nongenitourinary comorbidities that directly affect their medical and surgical treatment and quality of life, as they pass through puberty into adulthood (Grimsby et al., 2015).

Renal Function

The nadir creatinine value during infancy has proven to be a useful predictor of long-term renal function. If the nadir value is less than 0.7 mg/dL, renal function tends to be stable during childhood unless there is further renal compromise by pyelonephritis (Geary et al., 1986; Noh et al., 1999; Reinberg et al., 1991b). Reconstruction of the upper and lower urinary tract has been proven to maintain stabilized renal function in most patients (Lopes et al., 2015), but the importance of urinary tract monitoring by periodic imaging and cultures and prompt treatment of urinary tract infections, with or without prior surgery of the urinary tract, cannot be overemphasized. Unfortunately, the risk of infection is constant in the setting of persistent urinary tract dilation and stasis. Up to 30% of patients, generally those with impaired renal function at initial evaluation, develop chronic renal failure during childhood or adolescence (Geary et al., 1986). Furthermore, kidney dysplasia and polyuria may also play a deleterious role in the long-term renal function (Lopes et al., 2015). Renal transplantation is necessary for these patients to ensure normal growth and development, and success with transplantation in patients with PBS can be expected to equal that in other age-matched groups (Reinberg et al., 1989). Fusaro et al. (2004) have reported on five boys with PBS who underwent renal transplantation. The 5-year graft survival rate was 66.7%, with all maintaining their native urinary tracts.

The key to management of the urinary tract in the patient with PBS is individualization of care because some require major urologic reconstruction, and others require little if any intervention. Long-term surveillance of the urinary tract is essential because functional dynamics can change over time.

Bladder Function

As mentioned before, urodynamic studies of patients with PBS generally show normal compliance with decreased sensibility and contractile activity. As consequence, some patients tend to retain large volumes in the bladder, which develops progressive capacity associated to significant postvoid residual (Snyder et al., 1976). The lack of abdominal support, the eventual association of polyuria, and the negative behavior of some patients in regard to timed voiding usually increase this tendency (Kinahan et al., 1992). Therefore, to prevent further bladder dilation and upper urinary tract deterioration, all patients, even those who underwent lower urinary tract reconstruction and abdominoplasty, have to be trained as early as possible and constantly reinforced to empty their bladders on schedule, eventually associating it to double or triple voiding and Valsalva's or Credé's maneuvers. In the case of progressive unbalanced voiding, if such a program is not feasible or ineffective, intermittent bladder catheterization is mandatory, either per urethra or through a Mitrofanoff channel. Eventually, effective voiding is achieved with growth and improved proprioceptive sensation, as well as increased abdominal support. In the series of Lopes et al. (2015), 17.4% of the patients submitted to reconstruction of the urinary tract required intermittent catheterization through urethra or a Mitrofanoff channel. Rarely, some of these children reacquire normal voiding with good bladder emptying.

Growth and Musculoskeletal Development

Normal growth can be expected in most of the patients with normal renal function, although growth retardation in the absence of renal compromise was observed in one-third of patients in one series (Geary et al., 1986). Patients with the syndrome may present musculoskeletal abnormalities that impair function and cosmesis. As many patients now reach adulthood, these abnormalities gain significance (Loder et al., 1992). As the abdominal flaccidity, either after previous surgical repair or not, generally improves with age, there is no restriction to physical activities appropriate for the age of the patient. The correct use of corsets may be useful in this situation. Some sport activities, such as swimming, may reinforce the thoracic, limb, and even abdominal musculature, without exerting undue strain on the abdomen. Thoracic deformities, such as *pectus excavatum*, usually do not compromise pulmonary function in the older child and may show some improvement with growth and exercise. If not, thoracoplasty may be requested by some patients in early adulthood because of cosmetic reasons. Significant scoliosis and lordosis associated with the abdominal flaccidity may require orthopedic management early in childhood to stabilize and improve the condition. Ankle abnormalities are also detected early in infancy, and some are better treated surgically at that age. Hip abnormalities that impair correct ambulation may be identified late in childhood, sometimes requiring surgical treatment. In a recent study, older patients and their families were informed that the correction of musculoskeletal problems through abdominoplasty and/or orthopedic surgeries was the most common way for health providers to improve their patients' quality of life (Grimsby et al., 2015).

Sexual Function and Fertility

A normal pattern of secondary sexual development can be expected as hormonal production by the testes is preserved (Woodhouse and Snyder, 1985), but sexual function may be impaired by retrograde ejaculation. Spontaneous paternity has not been reported to date; therefore primary infertility is usually taken for granted. In a recent study, 15 patients with a mean age of 18.2 years, who underwent successful orchidopexy early in childhood, were evaluated in regard to fertility. Of these, 14 had both testes in the scrotum, and FSH, LH, and testosterone levels were normal in all patients; 8 patients were able to provide semen samples, 6 by antegrade and 2 by retrograde ejaculation. Of these patients 5 had spermatozoa in the specimen, and 4 of them had motile spermatozoa (Dénes et al., 2017). This and other promising works stress the fact that assisted reproductive techniques may be feasible in those having had successful early orchidopexy (Fleming et al., 2013; Kolettis et al., 1999).

Key Points: Long-Term Follow-Up

- Up to one-third of the patients may develop chronic renal insufficiency during childhood or adolescence.
- Recurrent pyelonephritis as well as renal dysplasia and polyuria are major factors associated with renal function decline.
- Adequate emptying of the bladder is necessary to avoid recurrent infection and prevent upper tract deterioration associated to poliuria.
- A normal pattern of sexual development is expected after orchidopexies, although no spontaneous paternity has been reported to date.
- There is significant spontaneous improvement of abdominal tonus in most cases with growth, but the skeletal abnormalities often require surgical correction.

Background

Few afflictions of the newborn male share in the irony of being readily diagnosed and treated with a straightforward initial surgical intervention, yet imply the significant long-term consequences of posterior urethral valves (PUVs). As the most common cause of bladder outlet obstruction in infants, the presentation of PUV is often rendered antenatally, and pathognomonic findings on postnatal imaging confirm the diagnosis. **Although an endoscopic ablation or urinary diversion will address the immediate uropathy, the embryologic insult to the bladder and kidneys is profound and requires that these infant boys remain under the extended care of urologists and nephrologists.**

Description

A congenital obstruction of the posterior urethra ascribed to valvelike leaflets was recognized as early as 1769, by Morgagni, then confirmed by Langenbeck in 1802, both based on postmortem dissections. It was Hugh Hampton Young, however, who described the first endoscopic diagnosis of a urethral obstruction that he termed “posterior urethral valves” (Young et al., 1919). Despite the rudimentary nature of the early endoscopic instruments, in 1920 Randall carried out the first endoscopic resection of valves, providing a description that remarkably encapsulates the visual findings of the posterior urethra even today (Randall, 1921):

> *The prostatic urethra is markedly dilated. The vesical neck raised and bladder orifice relaxed. Deep pittings penetrate down into either lateral wall of the prostatic urethra and at the extremity the verumontanum is seen a fine frenulum which extends distally for about 1 cm, and in dividing, forms what is apparently a definite valve on either side of the urethra, rising from the floor to each side wall.*

Young was the first to propose a classification system for the lesion in 1919 based on an initial 12 patients that remains a widely used contemporary nomenclature (Fig. 33.1). **The type 1 lesion, pertinent to 95% of cases, is theorized as a hypertrophied variant of the inferior urethral crest formed by the insertion of the distal ends of the Wolffian ducts into the**

anterolateral walls of the cloaca (Field & Stephens, 1974). **The urethral valves are actually leaflets that arise from the verumontanum, take an anterior course, and then fuse in the midline just proximal to the external striated urethral sphincter.** Some argue that the cleft seen in the midline—the "two forklike processes" as Young described, or the leaflets fanning out from the verumontanum—is actually iatrogenic and created by retrograde instrumentation in the perinatal period (Dewan et al., 1994).

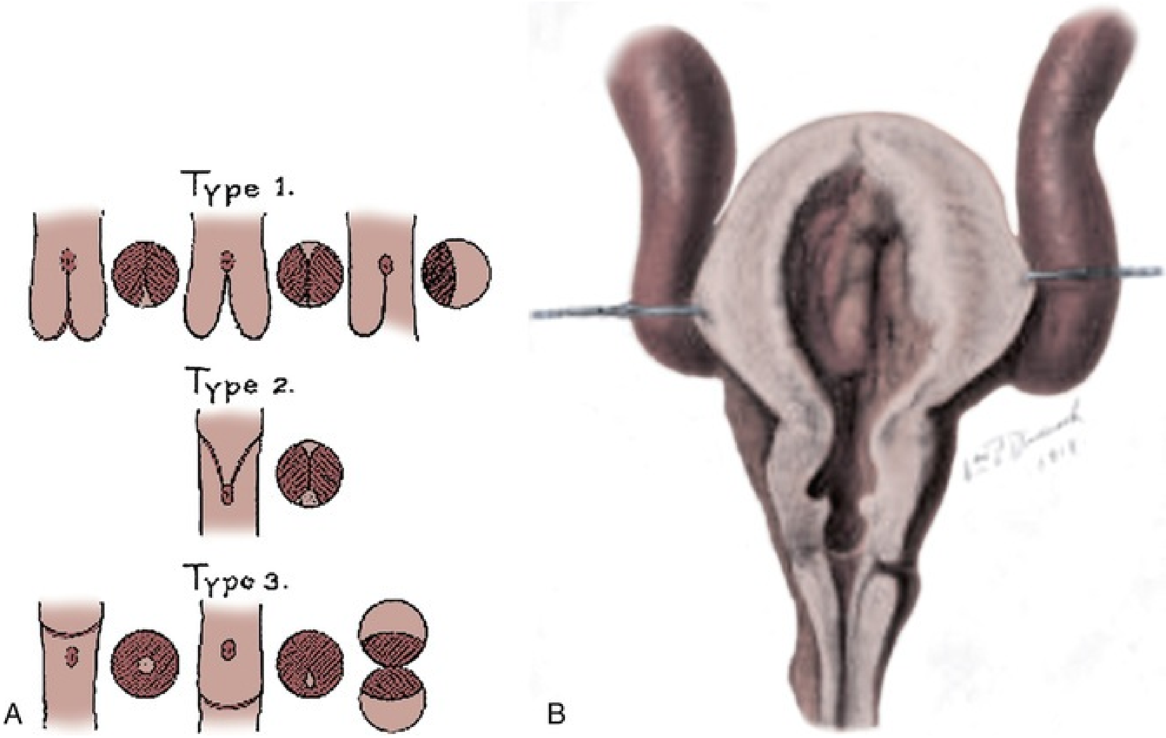

FIG. 33.1 (A) Young's original figures from his 1919 article describing three types of posterior urethral valves. (B) William P. Didusch illustrates the pathognomonic findings associated with posterior urethral valves: the thickened bladder with elevated bladder neck, dilated prostatic urethra, and the valve leaflets commonly ascribed to type 1 valves. The ureters are shown to be dilated. (From Young HH, Frontz WA, Baldwin JC. Congenital obstruction of the posterior urethra. *J Urol* 1919;3:289.)

The type 2 valve of Young, described as arising from the verumontanum and extending posteriorly and superiorly to the bladder neck, is not obstructing and **has not been reported definitively since early reports.** Stephens reported seeing no type 2 valves in 210 boys with PUV examined with cystoscopy and suggested that the description was that of the secondary effects at the bladder neck of more distal obstruction (Stephens, 1955).

The type 3 valve is another contentious diagnosis, but **is most commonly described as an annular ring similar to that seen with a congenital urethral stricture. Young described a complete obstruction “attached to the entire circumference of the urethra, there being a small opening in the center.”** The embryologic origin for this variant affecting 5% to 10% of cases of outlet obstruction is felt to be a persistence of the urogenital membrane after the urorectal septum divides the cloacal membrane (Stephens et al., 2002).

A consensus view on the embryologic origins of PUVs remains elusive, although various mechanisms have been proposed. The earliest theory held that hypertrophy of the urethral mucosal folds were the cause of obstruction, which was furthered later to suggest cloacal remnants caused the appearance of valves after division by the urogenital membrane (Krishnan et al., 2006). Lowsley placed the origin of PUVs in an abnormal development of the Wolffian and Müllerian ducts based on an autopsy study in 1914; but a more recent autopsy study corroborates the presence of what is termed a “congenital obstructing posterior urethral membrane (COPUM),” consistent with a persistent, oblique urogenital membrane that is punctured at the time of catheter or feeding tube placement in the immediate postpartum period by the medical practitioner (Dewan et al., 1994, Krishnan et al., 2006). Although the premise of COPUM is an interesting, even provocative hypothesis, convincing, corroborative evidence is lacking.

Genetic Basis of Posterior Urethral Valves

An understanding of the genetic etiology for PUVs is still in its infancy. Chiarmonte et al. reported a familial incidence of PUVs, identifying that affected siblings shared a partial duplication in the short arm of chromosome 11 (Chiaramonte et al., 2016). Other studies similarly implicated chromosome 11, along with chromosome 1 (Weber et al., 2005). The majority of cases described in the literature are sporadic, but **because the anomaly is known to affect siblings, inheritance of PUVs may be autosomal recessive, x-linked recessive, or by multifactorial inheritance. A recent genome-wide population-based study of copy number variants in isolated PUV identified novel candidate gene regions in 57% of cases examined** (Boghossian et al., 2016). Faure et al. examined the phenotypic effect of copy number variants in PUVs and concluded that affected children have a higher nadir creatinine and increased likelihood of progressing to stage V chronic kidney disease (Faure et

al., 2016).

Epidemiology

Congenital anomalies of the urinary tract affect up to 1 in 500 pregnancies, and obstructive uropathy accounts for most of these cases. (Lissauer et al., 2007; Ruano, 2011). A large population-based registry study from the United Kingdom demonstrated that lower urinary tract obstruction (LUTO) has an incidence of 2.2 per 10,000 births, of which PUVs was the most common pathology (1.4/10,000 births) followed by urethral atresia and prune-belly syndrome (Anumba et al., 2005). Because birth incidence requires the often inaccurate count of early spontaneous pregnancy loss, a latter study following a similar cohort based in the West Midlands between 1995 to 2007 calculated **a prevalence ratio of PUVs—number of affected births divided by the total number of live births and stillbirths—of 2.10 per 10,000 births** (Malin et al., 2012). This prevalence was also significantly higher in black and minority ethnic groups when compared with white Europeans.

A review of the Kids' Inpatient Database (KID)—a national database of inpatient pediatric hospitalizations in the United States—found 578 newborn males diagnosed with PUV between 1997 to 2009, that when divided by 10.0 million live male births in hospitals over that interval, gave a weighted prevalence rate of 1.6 per 10,000 in hospital live male births (Lloyd et al., 2013).

A more recent Australian study calculated a live birth incidence of PUVs as 1.28 per 10,000 in New South Wales. No association between PUVs and maternal or socioeconomic factors was found (Thakkar et al., 2014).

Considering that the United States alone may expect 300 to 500 new cases of PUVs born annually—of which one third will go on to end-stage renal failure (Heikkilä et al., 2011)—the economic repercussions in terms of dialysis and renal transplantation arising from this congenital anomaly are enormous.

Key Points

- Type 1 valves are the most common variant of PUVs, and appear as leaflets that arise from the verumontanum and fuse anteriorly just proximal to the external urethral sphincter.
- Type 3 valves present as a congenitally obstructing membrane that is likely

perforated at the time of the initial postnatal catheterization.

- The incidence of PUVs is between 1.6 to 2.1 per 10,000 births.
- There is an emerging understanding of the genetic basis for PUVs, particularly associated with chromosome 11 and copy number variants.

Pathophysiology of Posterior Urethral Valves

Although the initial treatment of PUVs—cystoscopy and valve ablation—is a relatively simple and reproducible procedure with adequate training, the bladder outlet obstruction during early fetal development creates downstream consequences that afflict an individual, often for a lifetime (Table 33.1). The long-term sequelae of valvular disease can be correlated to bladder dysfunction, renal dysplasia, polyuria, and multiple other anatomic and physiologic factors. Simply put, the bladder exposed to developmental obstruction becomes hypertrophied and empties well during the compensated phase. Over time, polyuria caused by renal dysplasia and continuing glomerular damage leave the bladder without adequate periods of bladder emptying, leading to decompensation. This phase leads to increased bladder residuals that are causally linked to exacerbation of hydronephrosis and further glomerular damage.

TABLE 33.1

Damage Caused by Posterior Urethral Valves

ORGAN	EFFECT	NATURAL HISTORY
Lung	Pulmonary hypoplasia	May be fatal in newborns; limited data on long-term natural history of survivors
Kidney		
Glomerular injury		
Obstructive uropathy	Reversible renal insufficiency	Usually improves with initial treatment but can recur with bladder dysfunction
Dysplasia	Irreversible renal insufficiency	Permanent level of renal damage that limits growth; leads to progressive renal failure and hypertension
Tubular injury	Inability to limit sodium and water loss	Progressive with age; nephrogenic diabetes insipidus
Bladder	Poor sensation, hypercontractility, low compliance, and eventual myogenic	Bladder problems are lifelong and change with age and

	failure all may contribute to incontinence and poor emptying	management
Ureters	Poor contractility and inability to coapt and transport urine	Many will improve initially, but most have chronic hydronephrosis

Lower Urinary Tract

It cannot be overstated that the potential comorbidities arising from PUVs—renal dysfunction, urine reflux, worsening hydronephrosis—are directly related to bladder dysfunction.

Understanding the embryologic impact of PUVs on bladder development—and subsequent bladder dysfunction—remains an area of continuing investigation. The storage and voiding of urine at high pressures has been simulated in fetal sheep and rabbit models in vitro to investigate the cascade of events effectuating bladder smooth muscle alterations**. Increased bladder compliance is seen following partial bladder outlet obstruction** (**Kirsch et al., 2003**), **and more compliant bladders (simulating the decompensated bladder) lead to more upper tract dilation. So increased bladder dilation places the upper urinary tract at risk.** This model, and the work of others confirmed that extracellular matrix elements line the detrusor smooth muscle cells of the bladder after obstruction—as noted in valve bladders (Workman and Kogan, 1990). Importantly, the pathologically significant elevated storage pressures must be distinguished from the normal neonatal and infantile elevated voiding pressures that are a normal feature of bladder development (Sillen et al., 1992).

There remains some controversy whether the changes in bladder morphology in the valve-affected bladder are reversible, as opposed to the phenotypic changes in neurogenic bladders that are more permanent (Hutcheson et al., 2004; Keating, 1994; Rink, 1994).

The deposition in the extracellular matrix causes altered contraction and passive relaxation of the bladder, which may cause multiple intracellular changes ranging from a reduction in detrusor blood flow causing ischemia to free radical toxicity. These changes alter the phenotype of detrusor muscle myosin bundles and actin-associated filaments (Ghafar et al., 2002; Shukla et al., 2004; Levin et al., 2005).

The valvular obstruction will also lead to marked dilation of the posterior

urethra, hypertrophy of the bladder neck, and flattening of the verumontaum with dilation of ejaculatory ducts—the pathognomic findings on voiding cystourethrogram of this diagnosis (Figs. 33.2A–D and 33.3AB). These changes seem to return to a more normal appearance after valve ablation as the offending distal obstruction is removed.

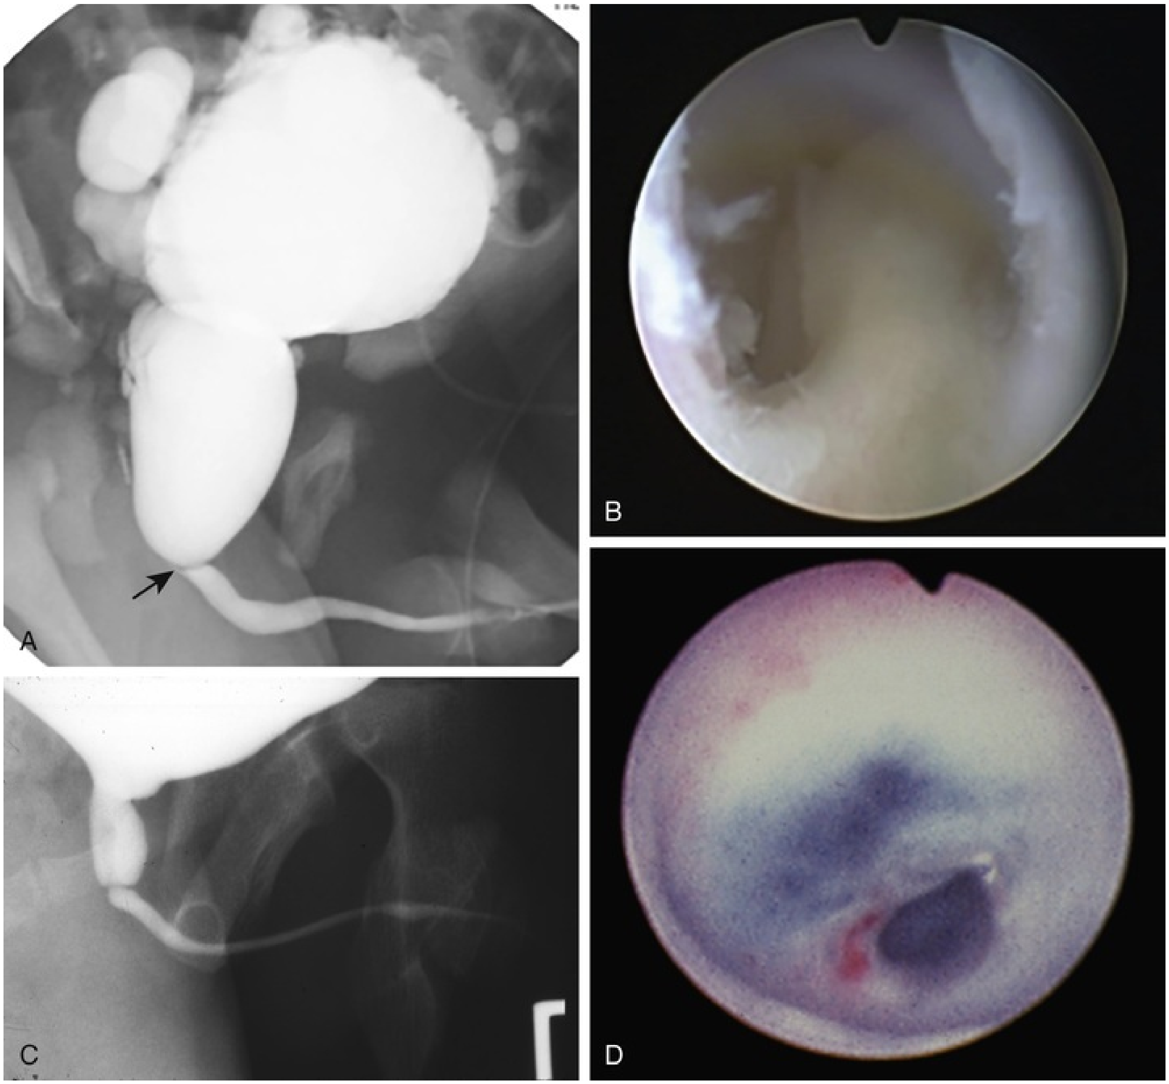

FIG. 33.2 (A) Voiding cystourethrogram image shows a bladder affected by multiple diverticuli and a dilated posterior urethra narrowing at the site of valvular obstruction. *Arrows* indicate valve leaflet that would be fulgurated at time of valve ablation. (B) Cystoscopic image corresponding to the point of obstruction in (A). The urethral valves are seen as leaflets arising from the verumontaum and fusing in the midline, just proximal to the striated sphincter. The verumontanum is noted just proximal to the valve leaflets. (C) Voiding cystourethrogram image shows an elevated bladder neck and dilated posterior urethral funneling to a point of obstructed flow. These are

typical radiologic findings of posterior urethral valves. (D) Cystoscopic image corresponding to point of obstruction in (A). The concentric narrowing is classically associated with a type 3 valve, but also considered consistent with the congenital obstructing posterior urethral membrane (COPUM) that may have been perforated at time of initial catheter placement.

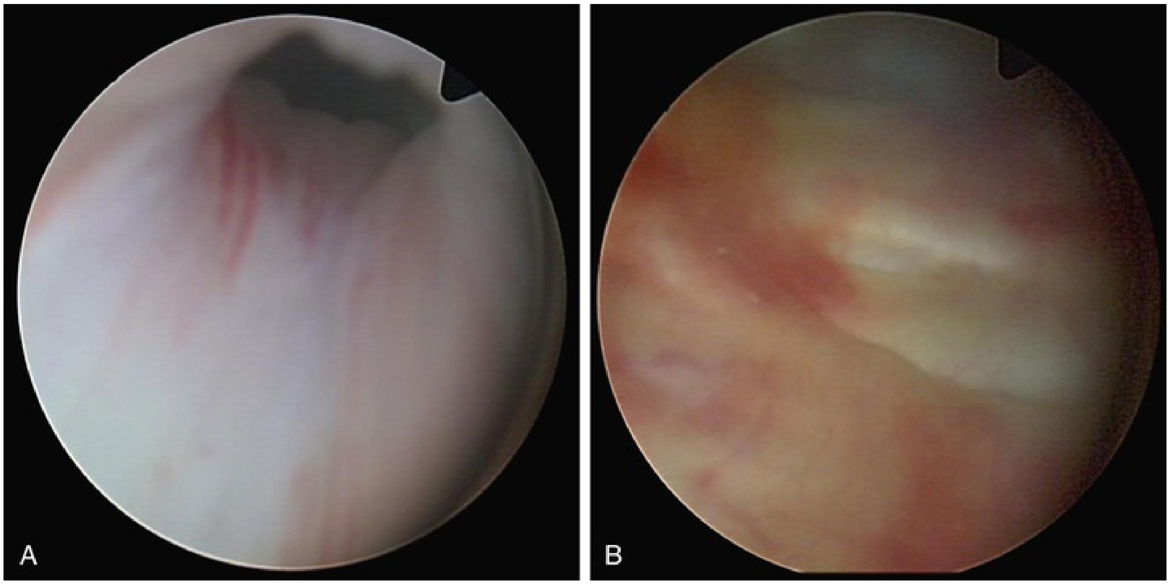

FIG. 33.3 Cystoscopic view in an infant with posterior urethral valves of (A) elevated bladder neck and (B) trabeculations in affected bladder consistent with obstructive uropathy.

Mitchell coined the term “valve bladder syndrome” in 1982, when he described 11 patients in whom bladder filling and emptying were noted to be intricately related to the extent of renal pelvicaliectasis and overall renal function and dysfunction (Mitchell, 1982). This concept was subsequently illustrated as a “vicious cycle” leading to the valve bladder syndrome. **Bladder hypertrophy secondary to fetal obstruction results in higher voiding pressures that maintain complete bladder emptying in the compensated phase. The increased voiding pressures lead to gradual remodeling of the bladder wall, increasing voiding pressures, and ultimately higher postvoid residuals (PVRs) as emptying begins to fail.** The rise in urine output with normal growth and development, combined with the latent polyuria of existing renal dysplasia and increased glomerular pressure caused by poor bladder emptying, conspire to increase urine volumes stored in the upper urinary tracts. As this bolus of urine fills the bladder, even as the bladder empties partially, a lack of extended periods of an empty, relaxed bladder push the compensated bladder toward decompensation. This, of course, leads to even greater PVRs, overflow incontinence, and further renal damage (Close et al., 1997). Underscoring the significance of the incontinence wrought by a valve bladder, Parkhouse et al. described a higher incidence of renal deterioration in boys presenting with incontinence after 5 years, even when renal function was normal in infancy (Parkhouse et al., 1988).

Upper Urinary Tract

A bladder exposed to PUVs undergoes a cascade of changes that alter the organ's normal function in storing and emptying urine. This bladder dysfunction manifests in varied ways during infancy, and will be discussed later in this chapter. **But what is apparent is that a sustained increase in intravesical storage pressures over prolonged time intervals transmits that pressure to the ureter, renal pelvis and, ultimately, the glomerular units—causing architectural and functional changes at each ascending structure** (Koff et al., 2002). These architectural changes can be inferred clinically by the severe hydroureteronephrosis that is often seen in the setting of PUVs. Increased echogenicity, parenchymal thinning with cortical cysts, and lack of corticomedullary differentiation similarly imply significant renal dysplasia (Fig. 33.4A).

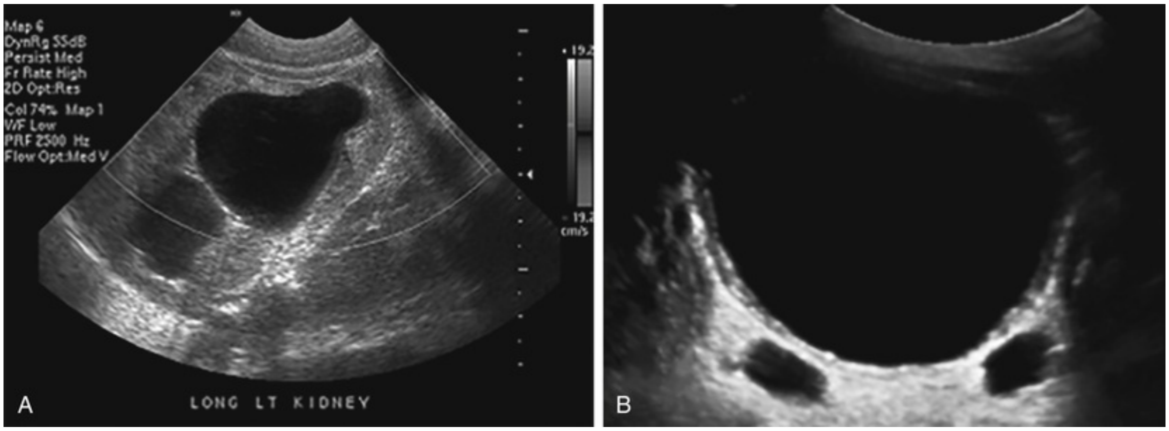

FIG. 33.4 (A) Left renal ultrasound for a newborn with posterior urethral valves. Severe pelvicaliectasis with thinning of the parenchyma with increased echogenicity, and loss of corticomeduallary differentiation is seen. (B) Pelvic view of the same patient, not yet catheterized, shows a distended bladder with dilation of bilateral distal ureters.

Ureteral dilation occurs as a direct transmission of pressure from the dysfunctional bladder and the vesicoureteral reflux that is seen in up to 70% of patients with PUVs (Puri and Kumar, 1996; Sarhan et al., 2011). Polyuria caused by progressive renal damage and congenital renal dysplasia compound ureteral dilation as well (Smyth et al., 1991). **The chronicity of ureteral dilation is classically believed to cause ureteral wall thickening, loss of peristalsis, and loss of mucosal coaptation, increasing the risk for urine stasis, infection, and increased pressures in the renal units** (see Fig. 33.4B; Parkhouse et al., 1988; Glassberg, 2001).

The elevated renal pelvic pressures secondary to increase in bladder and ureteral pressure lead to significant alterations in renal morphology and function. **The renal dysfunction seen in PUVs has two specific etiologies: (1) obstructive uropathy and (2) renal dysplasia.**

Obstructive uropathy causing renal damage is a well-known phenomenon in various models. Fetal sheep ureteral obstruction models clearly demonstrate that although hydronephrosis occurs rapidly after obstruction, irreversible dysplastic changes in the renal architecture are seen by term, and these changes were confirmed after bladder outlet obstruction in the same model (Peters et al., 1992; Chevalier, 2004). Apoptosis and increased oxidative stress in mouse kidneys with ureteral obstruction is also seen in the face of bladder outlet obstruction (Kawada et al., 1999; Chevalier, 2004).

The increased pressure from obstruction damages luminal cells in the renal tubules and also leads to poorly concentrated urine production (Li et al., 2004, Nguyen et al., 2005). Obstruction may also affect urinary concentration by reducing blood flow to the medulla, causing a loss in the medullary concentration gradient and resulting in significant polyuria, and even the postobstructive diuresis seen after catheter placement in infants with PUVs (Dinneen et al., 1995).

Although some debate about whether the entirety of renal damage seen in PUVs is actually a secondary phenomenon caused by obstruction, the observation that even early prenatal intervention does not necessarily forestall long-term renal disease posits that renal dysplasia may be concurrent with—rather than a consequence of—PUVs (Haecker et al., 2002). Others have demonstrated known primary dysplastic malformations of fetal cartilage tissue or dysplastic glomeruli and tubules in PUV–affected renal tissue at time of nephrectomy (Haecker et al., 2002).

A correlation between severe renal dysplasia with decreased activity of the renin-angiotensin system that modulates renal development has been noted in PUVs, and a decrease in the angiotensin receptor type 1 genetic polymorphisms (Peruzzi et al., 2005). Bajpai et al. found that plasma rennin activity increases precede common clinical findings of renal damage such as rising serum creatinine, renal scars, and lowering glomerular filtration rate (Bajpai et al., 2005). Although angiotensin II contributes to renal damage by hemodynamic alterations in glomerular flow, it also induces profibrogenic actions and inflammation through the induction of transforming growth factor-β_1 and tumor necrosis factor-α (Kagami et al., 1994; Furness et al., 1999; MacRae Dell et al., 2000). These cytokines are considered potential biomarkers that seem to decrease with improvement in renal function after valve ablation, and elevations imply worsening outcomes.

Administering an angiotensin-converting enzyme inhibitor (ACE-I) shows therapeutic potential in experimental studies by reducing fibrosis (Yu et al., 2004; Gagliardini and Benigni, 2006) and seems to reduce expression of biomarkers such as transforming growth factor-β_1 and tumor necrosis factor-α in another clinical study, suggesting a potential role in selected children with PUVs (Mandelia et al., 2013). Further corroborating the hypothesis that renal damage in valves is due, in part, to congenital dysplasia and not only obstruction, is the finding that the *ACE II* gene is expressed significantly more, and the angiotensin receptor gene *(ATR)* less, in patients with PUVs compared with those with other types of renal dysplasia and in controls (Peruzzi et al., 2005; Laksmi et al., 2010). Fetal sheep experiments, in contrast, demonstrated increased renin mRNA expression, angiotensinogen-2 mRNA along with upregulation of AT2 receptor expression with partial bladder outlet obstruction (Gobet et al., 1999). These alterations imply that renal dysfunction in children with PUV is multifactorial, and that both congenital renal dysplasia and secondary changes caused by obstruction in developing kidneys mediate the renal dysfunction that is a consequence of PUV.

Vesicoureteral Reflux and Dysplasia

Hoover and Duckett observed that the high-grade vesicoureteral reflux seen in children with PUVs was usually noted in an ipsilateral poorly functioning renal unit and that the contralateral renal unit appeared to have preserved renal function (Fig. 33.5) (Hoover and Duckett, 1982). **They hypothesized that the reflux served as a “pop-off” mechanism in which the dysplastic kidney with**

reflux served as a pressure reservoir mitigating damage to the contralateral kidney and coined the term, "vesicoureteral reflux and dysplasia (VURD)." This relationship, in that original series, was found in 13% of patients with valves, and the theory that these children would have better long-term renal function as a result of the pop-off phenomenon was widely affirmed.

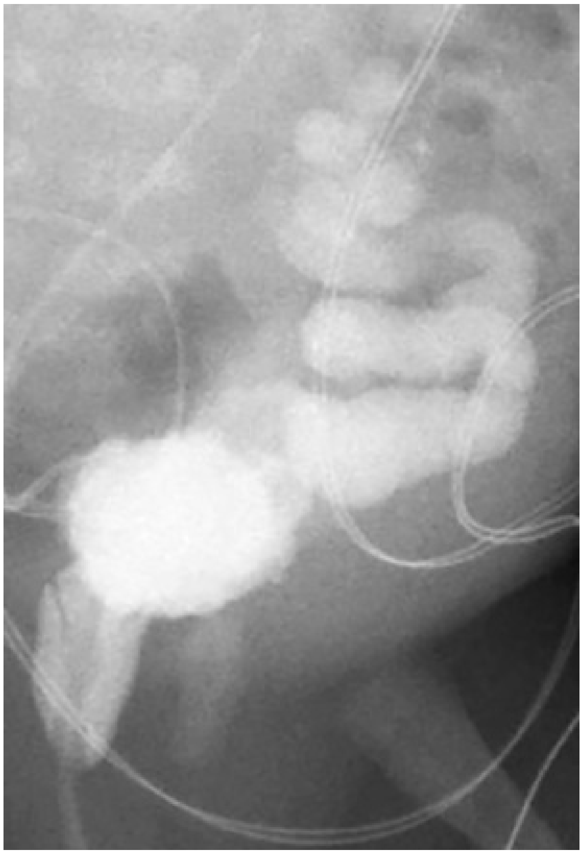

FIG. 33.5 Massive, dilating vesicoureteral reflux is seen on the left side on this voiding cystourethrogram and, in this case, is typically associated with a poorly functioning kidney on the ipsilateral side, referred to as the vesicoureteral reflux with dysplasia (VURD) syndrome.

Longer-term studies have confirmed, however, that the VURD does not improve renal prognosis. Fifteen years after the VURD was first described, Cuckow et al. found that although 67% of patients affected by VURD during the second year of life had a normal serum creatinine, only 30% of these children had normal values between 8 and 10 years of age (Cuckow et al., 1997). The glomerular filtration rate, importantly, was already abnormal in 75% of these patients, even in the first two years of life. Another observation that even the contralateral, nonrefluxing renal unit in VURD patients carries a high risk for congenital renal scarring (implying poorer long-term prognosis) means that VURD should never be allowed to create a false sense of security, and that close follow-up is mandatory, as with any cohort with PUVs (Narasimhan et al., 2005).

Key Points

- The renal dysfunction, vesicoureteric reflux, and voiding dysfunction seen in children with PUVs is mediated by a dysfunctional bladder.
- Renal impairment in PUV patients is caused by renal dysplasia and obstructive uropathy.
- The VURD syndrome confers no protective benefit on long-term renal prognosis.

Diagnosis

Antenatal Diagnosis

Ultrasonography

With widespread access to antenatal sonography, PUVs and other LUTOs such as urethral atresia or stenosis are increasingly detected during the fetal period**. PUV is detected in approximately 1/1250 ultrasound screenings, accounting for 10% of significant antenatally detected genitourinary disease and afflicting one third of surviving infants with bilateral renal disease** (Gunn et al., 1995; Thomas and Gordon, 1989). **The pathognomonic ultrasound findings of a thickened, dilated bladder along with bilateral hydroureter and pelvicaliectasis do carry a high sensitivity (95%) and specificity (80%), and oligohydramnios and the dilated posterior urethra displaying the "keyhole sign" further corroborate the presence of LUTO** (Figs. 33.6 and 33.7) (Peters, 1998; Robyr et al., 2005). Renal echogenicity will be increased in PUVs, and is a reliable indicator to infer renal damage as well.

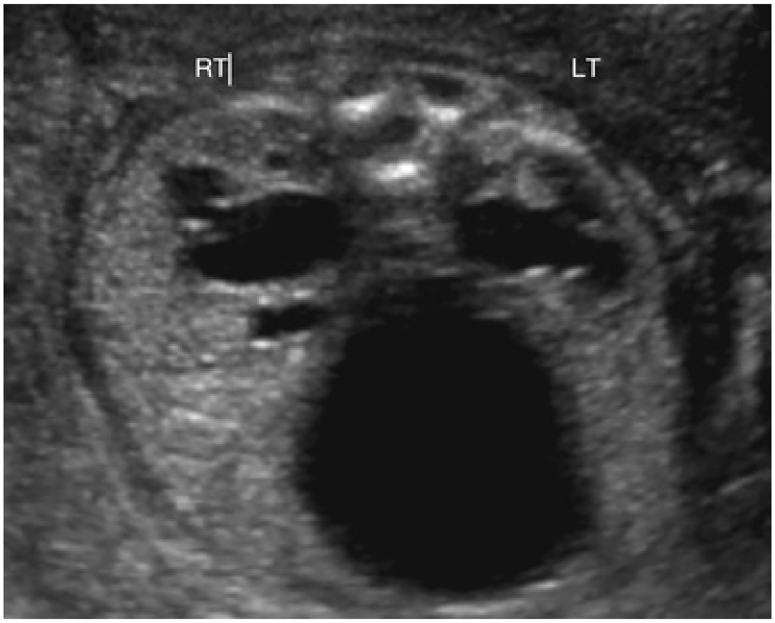

FIG. 33.6 (A) Antenatal ultrasound examination demonstrates bilateral severe pelvicaliectasis with dilated bladder in fetus. (Courtesy of Dr. Mark P. Johnson, Children's Hospital of Philadelphia.)

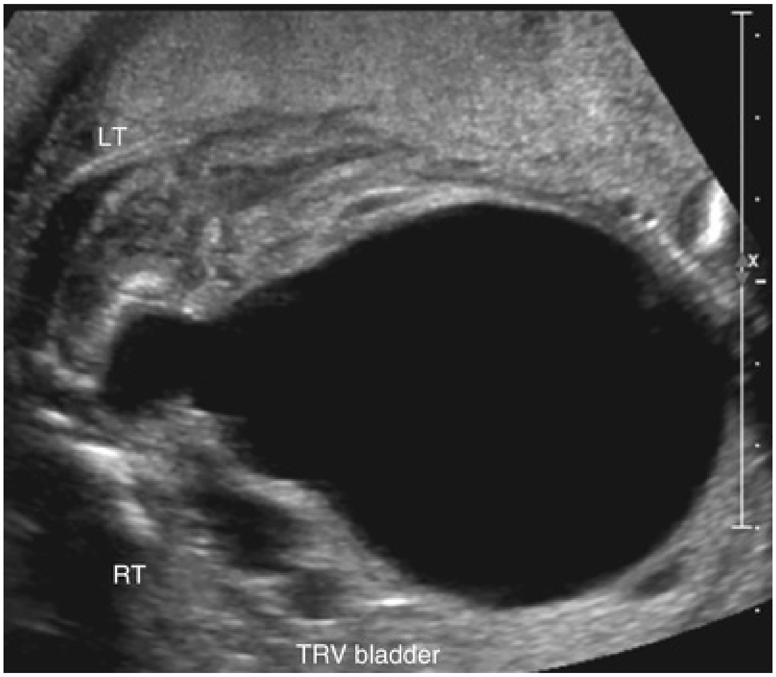

FIG. 33.7 Ultrasound of fetal bladder shows a thickened bladder with dilated posterior urethra below, suggesting the “keyhole sign.” (Courtesy of Dr. Mark P. Johnson, Children's Hospital of Philadelphia.)

Although LUTO may be diagnosed prenatally, differentiating valves from urethral atresia or prune-belly syndrome, high-grade vesicoureteral reflux or bilateral primary obstructing megaureters is much more problematic, reducing the accuracy of diagnosing PUVs with prenatal sonography alone to as low as 50% (Abbott et al., 1998). Still, **the antenatal finding of a thickened, enlarged bladder, bilateral ureterectasis with pelvicaliectasis with or without oligohydramnios in a male infant requires an early postnatal ultrasound and voiding cystourethrogram before the infant's discharge from the postpartum unit** (Lee et al., 2006; **Herndon, 2012**; St Aubin et al., 2013).

A review of all births with PUVs over 5 years in New South Wales, Australia, found that 53% of cases were diagnosed antenatally. Of the remaining births, one half were diagnosed in the neonatal period, and the other half presented with urinary tract infections (Thakkar et al., 2014).

Fetal Magnetic Resonance Imaging

Fetal magnetic resonance imaging (MRI) is an adjunct in prenatal diagnosis and increasingly available at major centers. As with ultrasonography, fetal MRI is used to distinguish the degree of obstruction based on urethral dilation, bladder distention with thickened bladder wall, and reduced amniotic fluid levels (Fig.

33.8). Lung hypoplasia and cystic changes in renal parenchyma are also apparent on MRI, although the rate of renal dysplasia does not necessarily correlate with microcystic or macrocystic changes (Chauvin et al., 2012). One study of fetal MRI in early gestation showed that the modality altered the initial sonographic diagnosis in 30% of the cases (Poutamo et al., 2000). **Although MRI does provide added information as to the cause of obstruction in select cases, the utility of MRI is limited as with sonography in diagnosing the actual cause of LUTO** (Miller et al., 2002).

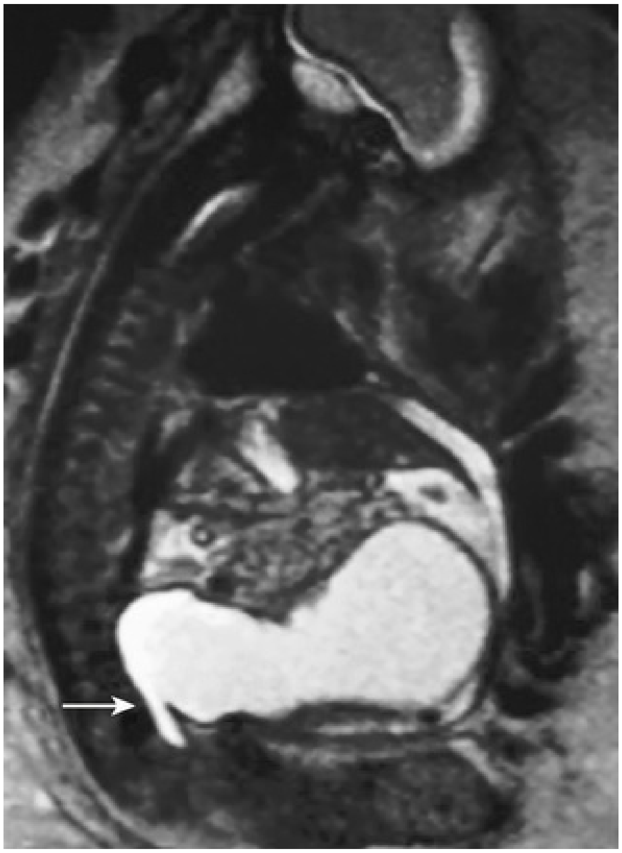

FIG. 33.8 Fetal magnetic resonance imaging demonstrating lower urinary tract obstruction that was postnatally diagnosed as posterior urethral valves. A dilated bladder funneling to a visible posterior urethra is seen on this T2 image *(arrow).*

Postnatal Diagnosis

Ultrasonography.

Much like the antenatal period, classic findings on ultrasound suggest PUVs are a distended bladder with thickened bladder wall, presence of bladder diverticula, dilated posterior urethra, and a high bladder neck with hyperplasia. The classic “keyhole sign” is often evident as well. These lower tract changes may be associated with upper tract changes such as a dilated ureter with or without dysplastic changes of kidney, which include cyst proliferation, loss of corticomedullary differentiation, and abnormal echogenicity. In the newborn period, a urinoma may be inferred by free fluid around one or both kidneys. In our practice, we consider a bladder wall to be thickened if it measures more than 3 mm when it is distended or more than 5 mm when it is empty.

Voiding Cystourethrography

The voiding cystourethrography remains the definitive radiologic study in confirming the diagnosis of PUV. This study should be completed in the early postnatal period after renal and bladder sonography and as soon as an infant with suspected prenatal findings of valves is hemodynamically stabilized and able to undergo the contrast study.

The bladder often appears thickened and trabeculated with multiple diverticuli, mimicking the appearance of a neuropathic bladder. High-grade vesicoureteral reflux may be seen in approximately 50% of patients with valves at the time of diagnosis (Hassan et al., 2003). **Images obtained during the voiding phase will show contrast traveling across a hypertrophied, elevated bladder neck and grossly dilated posterior urethra (Fig. 33.9AB).** The urethra funnels abruptly at a transverse membrane, or cusp, **representing the obstructing valve leaflets seen at cystoscopy. These are the pathognomonic signs for PUV.**

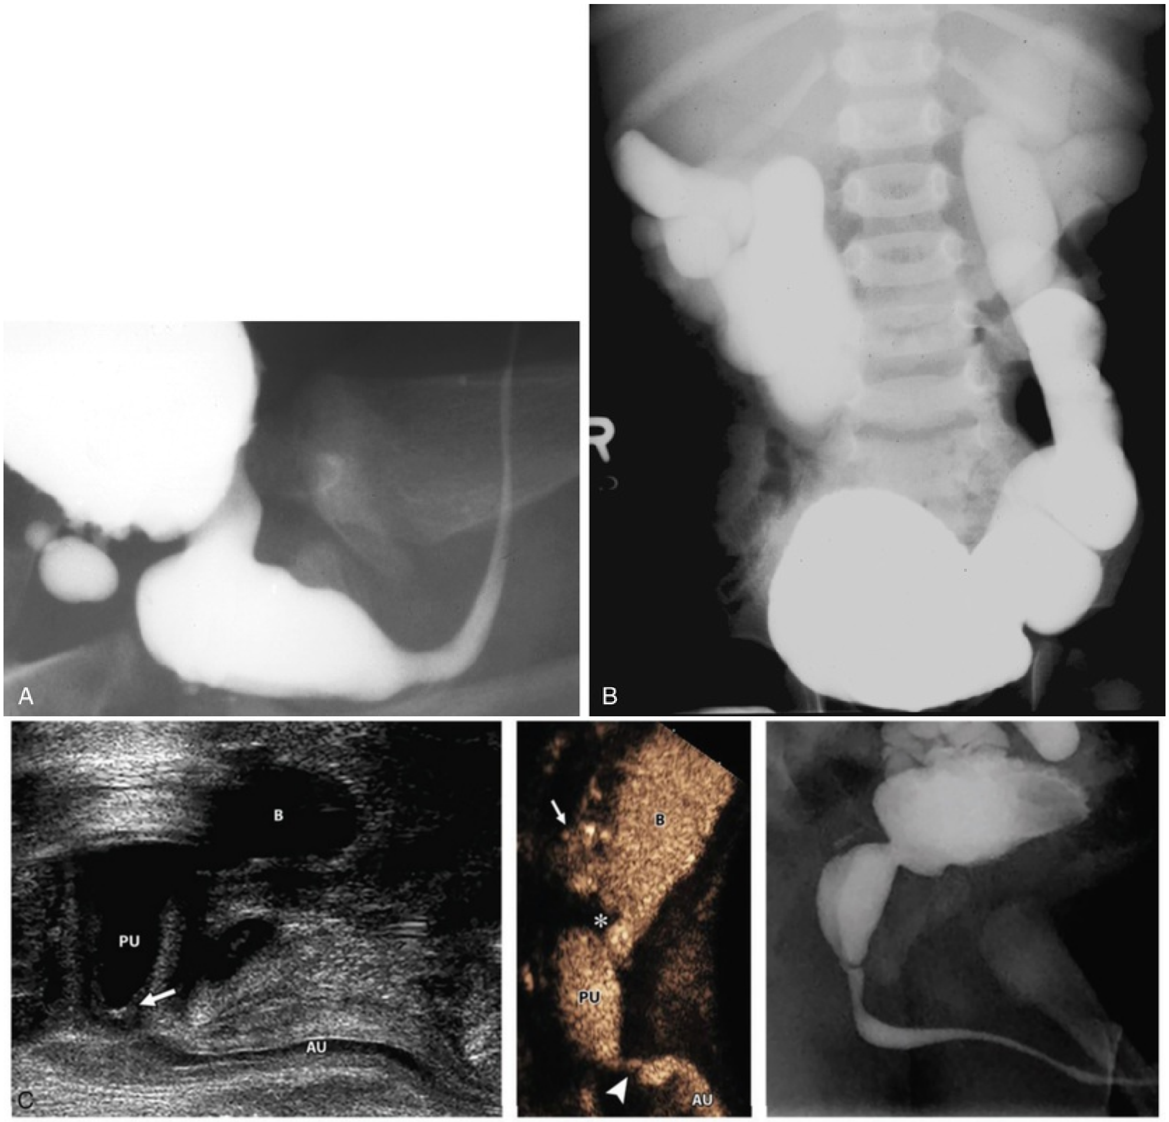

FIG. 33.9 (A) Voiding cystourethrogram image demonstrates a dysmorphic, elongated bladder with dilated posterior urethra and classic appearance of posterior urethral valves. (B) Dilating vesicoureteral reflux is seen bilaterally. (C) Contrast-enhanced voiding ultrasonogram (ceVUS) image of an infant with posterior urethral valves *(arrows; middle panel)* compared with standard sonography *(left panel)* and fluoroscopic voiding cystouretherogram *(far-right panel). B,* Bladder; *PU,* posterior urethra; *AU,* anterior urethra. (From Duran C, Beltrán VP, González A, et al. Contrast enhanced voiding urosonography for vesicoureteral reflux diagnosis in children. *Radiographics* 2017;37(6):1865.)

The study commences with the insertion of an 8-Fr feeding tube into the urethra, and this tube may curl within the capacious posterior urethra or hypertrophied bladder neck, requiring the use of a coudé catheter to advance into the bladder. Often a catheter may already be in place at the time of the study, and it is important that the catheter be withdrawn gradually distal to the posterior urethra during the voiding phase of the study to offer unobstructed views of that segment.

Voiding Urosonography (VUS)

Second-generation ultrasound contrast has enabled ultrasound-guided dynamic imaging of the lower urinary tract. This has been well established in the diagnosis of reflux with contrast-enhanced voiding ultrasonography (ceVUS) with some studies reporting sensitivity exceeding the present standard of care of fluoroscopic voiding cystourethrogram (Kis et al., 2010). This has led to an interest in imaging the urethra to diagnose urethral pathology. There is significant evidence today to use ceVUS for imaging the urethra and reliably diagnose PUV (see Fig. 33.9C) and other pathologic conditions such as a urethral diverticulum (Mate et al., 2003; Berrocal et al., 2005; Duran et al., 2009). At our institution, a significant proportion of lower urinary tract imaging is completed using contrast ultrasound–based imaging as a concerted effort to reduce radiation exposure in children and find it to be a useful modality.

Radionuclide Renal Scan

The radionuclide renal scan offers quantification of differential renal function, and cortical deficits seen on the study may imply renal dysplasia when completed in the neonatal period. Mercaptoacetyltriglycine (MAG3) is a useful agent to evaluate renal functional contribution, although delayed emptying of nuclear tracer from the often dilated collecting systems should not be necessarily interpreted as ureterovesical junction obstruction requiring intervention. Placement of a urinary catheter is essential in a patient with vesicoureteral reflux to minimize error in the calculation of renal function.

Laboratory Evaluation

Laboratory evaluation of a newborn with a diagnosis of PUV will, as with any newborn, reflect maternal values and must be interpreted with caution. After 48 hours, the maternal blood mediated through the placenta should clear, and the infant's kidney baseline function will be apparent. Both these values represent the infant's baseline values, and subsequent values and trends may be monitored to infer effective renal function. The nadir creatinine value at various intervals—1 month of age, 6 months of age, and 1 year of age—are considered important diagnostic tools, and this value may be plotted to evaluate immediate response to treatment in the neonatal period. But the serum creatinine plateau even in unaffected children may not be seen until days 65 and 220 of life (DeFoor et al., 2008; Boer et al., 2010).

Key Points

- Antenatal diagnosis is primarily by fetal ultrasound sometimes aided by fetal MRI. Combination of thickened dilated bladder with upper tract dilation along with oligohydramnios has a high sensitivity for PUVs.
- Postnatal diagnosis is with ultrasound and finding confirmed by fluoroscopic voiding cystourethrogram. More recently, contrast-enhanced VUS is emerging as a good alternative.
- Biochemical evaluation centers on electrolyte and creatinine values. Nadir creatinine value is en effective prognostic indicator for long-term kidney function.

Clinical Presentation and Initial Management

Antenatal Presentation and Management

With widely available advanced ultrasound technology, a significant proportion of children with PUVs are diagnosed antenatally and may present to the urologist for prenatal advice and management. Along with the previously discussed common markers of bladder outlet obstruction, important considerations are the presence of oligohydramnios, degree and laterality of hydronephrosis, and gestational age.

Antenatal intervention in cases of suspected LUTO was popularized in the mid-1980s (Glick et al., 1984, 1985) as advances in fiber optics and endoscopic miniaturization enabled even complex fetal procedures. Although ultrasound remains the mainstay of diagnosis in the antenatal period, fetoscopy has been shown to offer better sensitivity than ultrasound, although with the considerable additional risks of intervention (Welsh et al., 2003). **Historically, intervention is considered in some centers when antenatal sonography detects evidence of oligohydramnios, a dilated bladder, and severe hydroureteronephrosis—without renal cortical cystic lesions—in a fetus with a normal karyotype** (Ruano, 2011). A fetal urine sample obtained after 20 weeks' gestation demonstrating **favorable prognosis is suggested by a urinary sodium <100 mEq/L, chloride <90 mEq/L, osmolarity <200 mEq/L, and β_2 microglobulin <6 mg/L** (Nicolini and Spelzini, 2001). **Johnson et al. showed that triple serial sampling in 48- to 72-hour intervals is a more accurate proxy to assess irreversible renal damage, with sequential rises in values of the above variables portending an unfavorable prognosis** (Johnson et al., 1994).

The Society of Fetal Urology held a multidisciplinary panel discussion in 2016 on appropriate patient selection for antenatal intervention (Farrugia et al., 2017). The panel suggested a standardized classification based on the severity of LUTO based on various factors. Ruano et al. suggested stratifying antenatally detected bladder outlet obstruction into discrete categories, with the most favorable outcomes associated with intervention in a fetus with: (1) oligohydramnios, but absence of anhydramnios; (2) severe hydronephrosis; (3) favorable fetal urine biochemistry; and (4) absence of renal cortical cysts (Ruano et al., 2016). Peters urged selective cautious intervention, given that some children do well in spite of significant obstruction and others might be taken through the intrauterine period by these interventions but ultimately not fare well.

Nevertheless, vesicoamniotic shunting to treat oligohydramnios offers potential ameliorative effects on pulmonary function and represents the first stage in fetal intervention with several hundred shunt procedures reported in the literature (Ruano, 2011). This approach is corroborated by fetal sheep models demonstrating that restoration of amniotic fluid volume prevents lung hypoplasia, although the lack of controlled studies in the literature constrains conclusions as to its effectiveness (Kitagawa et al., 2006).

And although a systematic review demonstrated a survival advantage in infants having undergone vesicoamniotic shunting, randomized trials were lacking (Clark et al., 2003). The percutaneous vesicomaniotic shunting versus conservative management for lower urinary tract obstruction (PLUTO) trial attempted to fill this paucity of data but was limited by poor recruitment and pregnancy terminations, with only 12 live births in each group studied. The results showed a trend toward improved survival at 28 days in the shunted group, but overall survival was very poor in both groups, with only two infants surviving to 2 years of age with normal renal function. There was a high mortality as a result of pulmonary hypoplasia. There was also a greater risk for pregnancy loss in the shunt group caused by procedure-related complications and early rupture of membranes (Morris et al., 2013).

There have been no studies similar to the PLUTO trial attempted for even more complex fetal interventions such as fetal cystoscopy with valve ablation or even fetal surgery. Fetal cystoscopy, performed using a 1.0-mm fetoscope, is carried out in an antegrade fashion by a transuterine percutaneous incision into the bladder. When the posterior urethra is entered through the bladder neck, a ND:YAG laser, or cauterizing wire, is used to perforate the obstructing membrane (Quintero et al., 1995, 2000; Ruano, 2011). Holmes et al. reported a series of 14 fetal surgical procedures for PUVs including antenatal valve ablation, vesicoamniotic shunting, cutaneous ureterostomy, and vesicostomy (Holmes et al., 2001). Six infants died as a result of premature delivery and respiratory failure, and 5 of 8 surviving children at a mean 11.6 years follow-up were in renal failure. The 43% fetal mortality rate for fetal surgery must be an essential part of any prenatal counseling before considering fetal intervention that offers potential, although yet unproven, benefits for a very select group of pregnancies.

Parental counseling for the possible diagnosis of PUVs is an important role that the pediatric urologist performs in the setting of antenatal diagnosis. In this role, we take the opportunity to educate parents about possible outcomes, possible diagnoses, expected course for the rest of the pregnancy, and where the child should be delivered, and we plot management once the child is born to broadly explain prognosis. It is an important role that reassures parents that all care is taken to provide their child the best care possible. Parents' perception of adequacy of information should be sought and any gaps of knowledge bridged. A recent study on patient perception of counseling shows a work in progress (Marokakis et al., 2017).

Key Points

- Up to 50% of infants with PUVs are diagnosed in the antenatal period.
- Severity of obstruction can be objectively assessed by the volume of amniotic fluid, degree of renal dysplasia, and fetal urinary makers.
- Vesicoamniotic shunting may have a survival benefit for the infant in select cases, but there is no clear benefit in the risk for renal failure.

Postnatal Management

Infants with PUVs may be affected by serious comorbidities such as pulmonary hypoplasia and physical stigmata of oligohydramnios, including Potter facies, club feet and deformed hands, and poor visceral muscle tone, and they may require intensive initial management. The infant may be noted to have difficulty with voiding, and the urinary stream may be weak or intermittent. A 5- or 7-Fr feeding tube, or similar-caliber urinary catheter, should be inserted per urethra in an infant presenting to the neonatal intensive care unit with a presumed diagnosis of LUTO. **Catheter placement into the bladder may be impeded by the hypertrophied and often elevated bladder neck and curling of the catheter within the dilated posterior urethra. In such cases, a coudé tip catheter, or alternatively, using a stylet to curl the tip of the feeding tube dorsally, will facilitate bladder drainage.** Minimizing any type of catheter balloon filling is important to prevent inducing bladder spasms in the small, hypertrophic bladder and potentially occluding the ureteral orifices (Jordan and

Hoover, 1985). Placement of the catheter within the bladder may be confirmed by bladder sonography, or in some instances, a one-shot cystogram.

An important consideration is that infants with PUV may be diagnosed with hyponatremia, sometimes triggered by a urinary tract infection. The hyponatremia is readily corrected with sodium supplementation and may be secondary to a transient pseudohypoaldosteronism (Deshpande 2018).

Pulmonary Hypoplasia

Although the focus in PUVs is too often on the lower urinary tract and kidneys, the most profound complication, and cause of perinatal mortality in infants affected by severe LUTO remains pulmonary hypoplasia. The often cyanotic baby requires complex ventilatory support and is often the factor delaying definitive surgical intervention to address the valves. Pulmonary hypoplasia seen in infants with a history of antenatally detected oligohydramnios may be the contributing factor to perinatal mortality in these children, requiring intensive and rapid supportive treatment (Pinar, 2004).

The association between PUVs, oligohydramnios, and pulmonary hypoplasia is recognized, but the etiology of hypoplasia is unclear and likely multifactorial. Grossly hydronephrotic kidneys and a dilated bladder combined with increased uterine pressure on the developing fetus caused by oligohydramnios may reduce diaphragmatic expansion and affect lung volume and growth (Fig. 33.10). This reduced expansion adversely affects the development of the fetal pulmonary tree that requires intraluminal pressure, volume, and flow while providing cellular signaling to the developing alveoli (Husain and Hessel, 1993; Laudy et al., 2002).

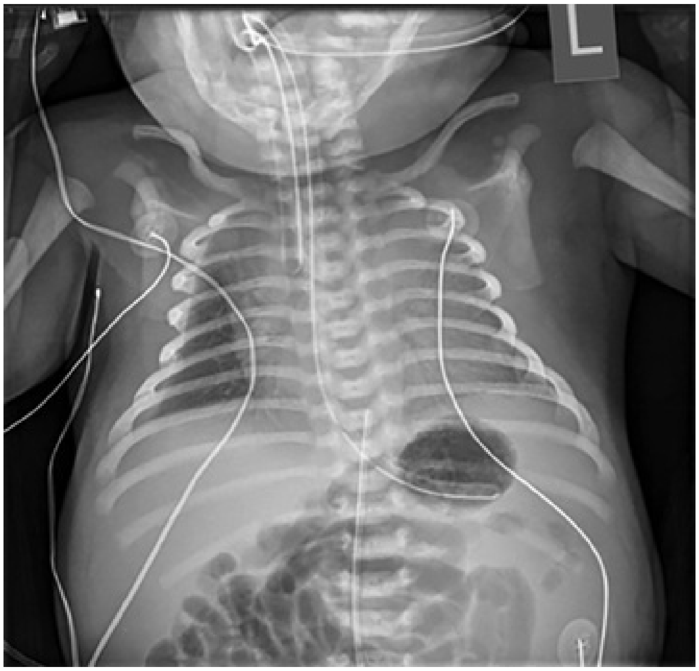

FIG. 33.10 Plain radiograph of a 5-day-old infant with posterior urethral valves and bronochopulmonary dysplasia, requiring airway support, shows reduced lung volume and left upper and lower lobe atelectasis.

Urinomas

A urinoma is associated with PUVs in 3% to nearly 10% of cases (Fig. 33.11) (Greenfield et al., 1982; Patil et al., 2003). The introduction of renal ultrasonography since 1979 increased the detection of urinomas to 15% in one study (Heikkilä et al., 2011). Forniceal rupture will appear on renal ultrasound as distorted renal parenchyma caused by fluid trapped within the renal capsule, and transperitoneal transudation of fluid or bladder rupture will present as neonatal ascites (Greenfield et al., 1982). Although voiding cystourethrogram or radionuclide cystography may delineate the site of leakage for ascites, the cause is often difficult to determine (Patil et al., 2003).

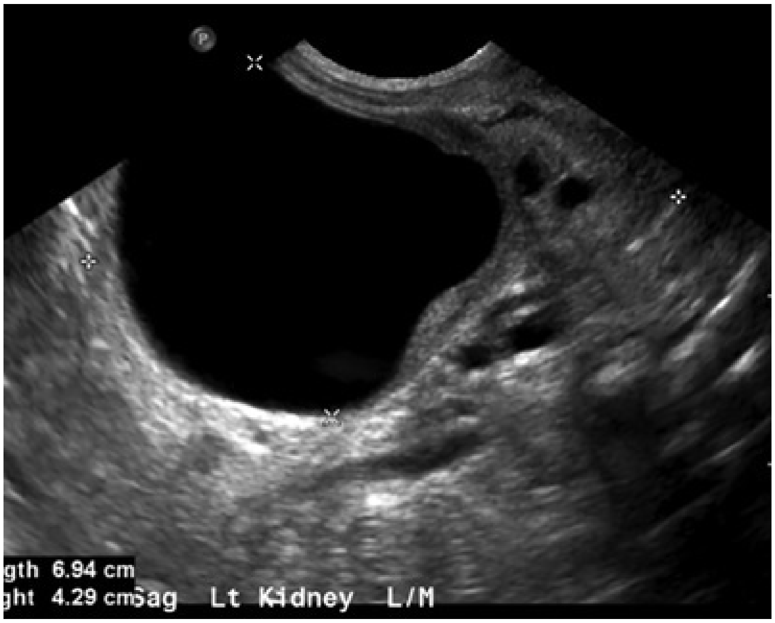

FIG. 33.11 Sonographic image of left kidney in a newborn diagnosed with posterior urethral valves shows a large urinoma. The urinoma compresses the renal parenchyma inferiorly, and is contained within the renal capsule.

Urinomas are usually addressed by restoring urinary flow and treating the proximate cause of LUTO, allowing the fluid to be reabsorbed. It is only in cases in which the ascites is causing respiratory distress, severe abdominal distension, or other clinical symptoms that percutaneous drainage or tapping ascites becomes necessary, but these interventions are uncommon.

There is some debate as to whether a urinoma heralds better or worse renal function for the affected side. Numerous studies have postulated that the urinoma serves as a pop-off mechanism, thereby reducing renal dysplasia on a given side, and others demonstrate globally preserved renal function, including an index of long-term renal severity (Rittenberg et al., 1988; Wells et al., 2010). Others hold that the urinoma, especially one retained within the renal capsule and compressing the kidney, impairs ipsilateral renal function and is a harbinger for worsened renal prognosis or has no bearing at all on long-term renal function (Patil et al., 2003; Kleppe et al., 2006; Heikkilä et al., 2011).

Delayed Presentation

In the age of extensive antenatal ultrasonography, delayed, postinfancy presentation of PUVs is assumed to be less common. Still, Engel et al. reported that 141 of 228 (62%) children undergoing valve ablation presented with PUVs with a clinical presentation other than prenatal hydronephrosis or oligohydramnios (Engel et al., 2011). Up to 64% of these children had a normal prenatal ultrasound, and most presented with urinary tract infections, voiding complaints, and acute renal failure in 10% (Engel et al., 2011). Another recent study at the Children's Hospital of Philadelphia followed a cohort of 138 patients presenting with PUVs between 1988 and 2011, of which 60 (43%) presented after 6 months of life (Pulido et al., 2014). **A high degree of suspicion for PUVs is therefore still warranted in boys presenting with lower urinary tract symptoms, especially recurrent urinary tract infections, but also overflow incontinence, gross hematuria, renal dysfunction, and less commonly, ejaculatory dysfunction** (Bomalaski et al., 1999; Schober et al., 2004). A renal ultrasound in these patients often detects the telltale bladder wall thickening, distal ureteral dilation that requires a voiding cystourethrogram for confirmation.

Key Points

- Antenatal finding of a thickened bladder and bilateral ureterectasis should be evaluated with early postnatal ultrasound and voiding cystourethrogram.
- Voiding cystourethrogram in valve patient will show bladder wall irregularity; hypertrophied, elevated bladder neck; and dilated and elongated posterior urethra.
- The most common cause of early mortality in infants with PUVs is pulmonary hypoplasia.

Surgical Intervention

Valve Ablation

Today, cystoscopy with ablation of PUVs is considered the preferred initial surgical option in any neonate diagnosed with PUVs. The treatment goal is to restore flow of urine through the urethra and enable normal cyclic filling and emptying of the bladder, which is superior to urinary diversion and passive urine drainage (Smith et al., 1996; Close et al., 1997). Experimental models corroborate clinical evidence of the importance of bladder cycling, and one model of urinary diversion and undiversion demonstrated the changes that occur in a diverted bladder prevented from cycling (Chun et al., 1989). A fetal sheep model developed an increase in expression of extracellular matrix elements and apoptosis after a high diversion (Chun et al., 1989).

There are several approaches to valve ablation. Historically, it had even been successfully performed with a crochet hook passed retrograde into the urethra and feeling the hook catch the obstructing tissue. Innes Williams first described the engagement of valves with a hook, and Whitaker and Sherwood modified the hook by insulating the wire except for the very distal portion of the hook, which measures 6 to 7 Fr and could be passed at the bedside without general anesthesia while applying a small amount of diathermy when ablating the valves (Whitaker and Sherwood, 1986).

With the miniaturization of endoscopes in the age of fiberoptic and, now, digital technology, cystoscopy can be accomplished in even the smallest neonate, and endoscopic valve ablation is the preferred approach at most centers today. **Availability of a 7.5-Fr or 9-Fr infant cystoscope with an offset lens facilitates passage of a variety of ablating devices, including a Bugbee electrode that can be used to incise the valves at the ventral 5 o'clock and 7 o'clock positions with or without an incision on the dorsal 12 o'clock position. Alternatively, a 12 o'clock alone might suffice** (Video 33.1). A wire bent at the tip and passed through a 3-Fr ureteric catheter is another option, as is the visually guided fogarty embolectomy catheter (Soliman, 2009). In an infant with a normal caliber urethra, the 9.5-Fr resectoscope may be used with a Collins knife working element (Fig. 33.12).

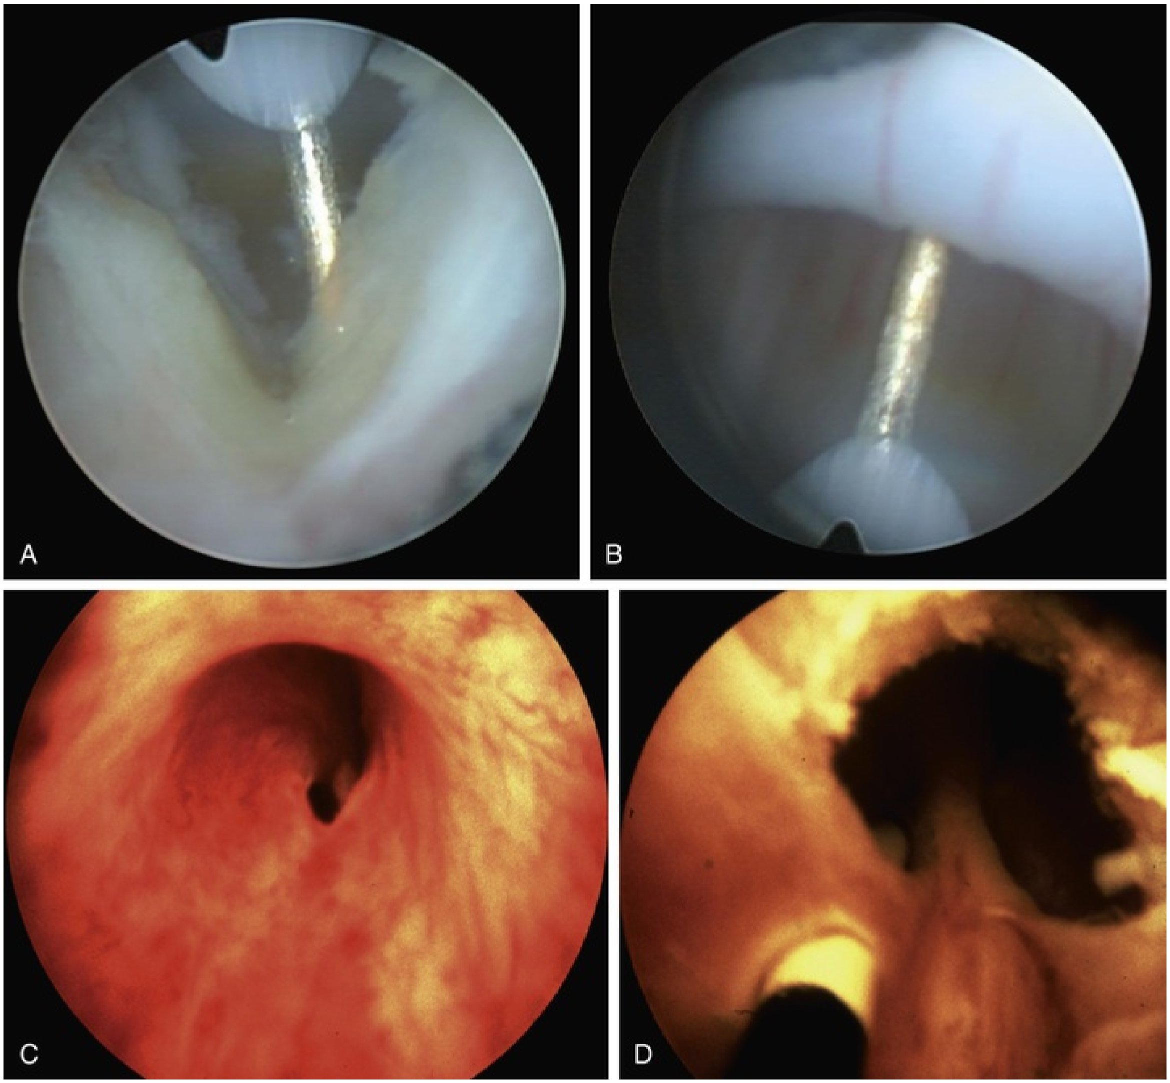

FIG. 33.12 Cystoscopic images of incision of posterior urethral valves. Incision with a Collins knife being made at the 5 o'clock position (A) and at the dorsal 12 o'clock position (B). Before incision (C) and after incision (D) with Bugbee wire. The ureteral catheter has been passed through a perforation in the valve leaflet.

Valves are thin and associated with minimal vascularity, and aggressive resection should be avoided. Use of a hot loop resectoscope for valve ablation, primarily in older children where a resectoscope can be readily inserted, seems to be associated with a higher risk for urethral stricture, and caution should be exercised with its use (Sarhan et al., 2010).

A urethral catheter is typically placed for at least 24 hours after the procedure and is not necessary to be kept longer, although it is not uncommon for the catheter to be left in for a longer period while the infant continues to be monitored for improvements in renal parameters or respiratory issues, often in an intensive care environment. A voiding cystourethrogram must be repeated after valve ablation within 1 month to ensure that the valves are no longer visible. It is not uncommon to see immediate signs of diminished bladder pressures, including some improvement in renal dilation and in the volume of vesicoureteric reflux.

Bladder neck hypertrophy and the subsequent elevation of the bladder neck proximal to the posterior urethra, along with the incomplete emptying that seems to persist on imaging in some boys after valve ablation, prompted an interest in transurethral incision of the bladder neck during or after primary valve ablation. The earliest reports of procedures to address this bladder neck hypertrophy included a Y-V plasty and bladder neck incision (Bauer et al., 1979). But subsequent to Mitchell's elaboration of the concept of the valve bladder, the concept was widely accepted as a plausible explanation for persistent bladder dysfunction in children with a history of PUV. Still, the concept of bladder neck obstruction and bladder neck incision is still offered as a surgical option (Androulakakis et al., 2005; Kajbafzadeh et al., 2007). Although some studies confirm that the bladder neck incision benefits emptying in children with a neurogenic bladder, the concerns of retrograde ejaculation and lack of improvement compared with controls in even short-term pilot studies have limited the adoption of this technique (Christensen et al., 1985; Sarin and Sinha, 2013). There is a dearth of studies from multiple institutions confirming the extended durability and advantage of bladder neck incision. One long-term study limited to 21 patients older than 18 years of age who underwent bladder neck incision in infancy reported no incontinence in adulthood and a lack of significant ejaculatory dysfunction (Keihani et al., 2017). Injection of botulinum toxin (Botox) into the hypertrophied bladder neck is another postulated modality proposed to address bladder dysfunction in PUVs—and it too failed to improve voiding dynamics in affected boys (Mokhless et al., 2014)

Vesicostomy

With miniaturization of endoscopic technology, vesicostomy is reserved primarily for the very low birth weight infant whose urethra cannot accommodate an endoscope and for a child with continued impaired renal function, high bladder urine volumes, and upper tract deterioration after valve ablation or urethral catheterization. The vesicostomy does reduce bladder storage pressures and may optimize glomerular filtration rate in some cases (Kim et al., 1997). The argument that the vesicostomy defunctionalizes the bladder and leads to decreased compliance in the long term has been refuted, as a properly created vesicostomy allows bladder filling and preserves contractile function as urine must be expulsed through the stoma, albeit at a reduced leak point pressure (Hutcheson et al., 2001). The vesicostomy is best seen as a temporary diversion in children with PUVs as it does not alter clinical outcomes as compared with primary ablation, nor does it prevent a bladder from acting as an adequate reservoir for renal transplant (Fine et al., 2011).

The vesicostomy is classically created with a 2-cm midline transverse incision made midway between the pubic symphysis and the umbilicus. The rectus muscles are separated, the bladder is exposed with traction sutures, and the peritoneum is mobilized cephalad and away from the posterior wall and dome of the bladder. The bladder dome is identified by isolating the urachus, which is ligated, so that the dome can be exposed through the fascial incision. The urachus and small portion of the bladder dome are excised, and then the detrusor is sutured to the fascia 1 cm below the edge of the cystotomy. **The key operative step in creation of the vesicostomy is to ensure that the posterior wall of the bladder is taut—accomplished by bringing the dome of the bladder to the skin—to prevent prolapse of the back wall of the bladder through the incision** (Fig. 33.13; Hutcheson et al., 2001).

Saunders; 2002.)

Upper Tract Diversion

Proponents of supravesical urinary diversion hold that direct decompression of the kidney by a cutaneous ureterostomy or pyelostomy will effectuate direct, low-pressure urinary drainage, allowing optimization of renal function (Fig. 33.14). High diversion, when renal dilation and biochemical markers of renal function fail to improve despite maximal bladder drainage, historically was felt to protect the upper urinary tract from ureterovesical junction obstruction caused by a tortuous intramural ureter passing through a thickened valve-affected bladder. In these cases, a loop diversion of the ureter or renal pelvis, for example, also allows bladder filling and bladder cycling, mitigating the concern of defunctionalizing the bladder (Pinto et al., 1978; Churchill et al., 1990; Kim et al., 1997).

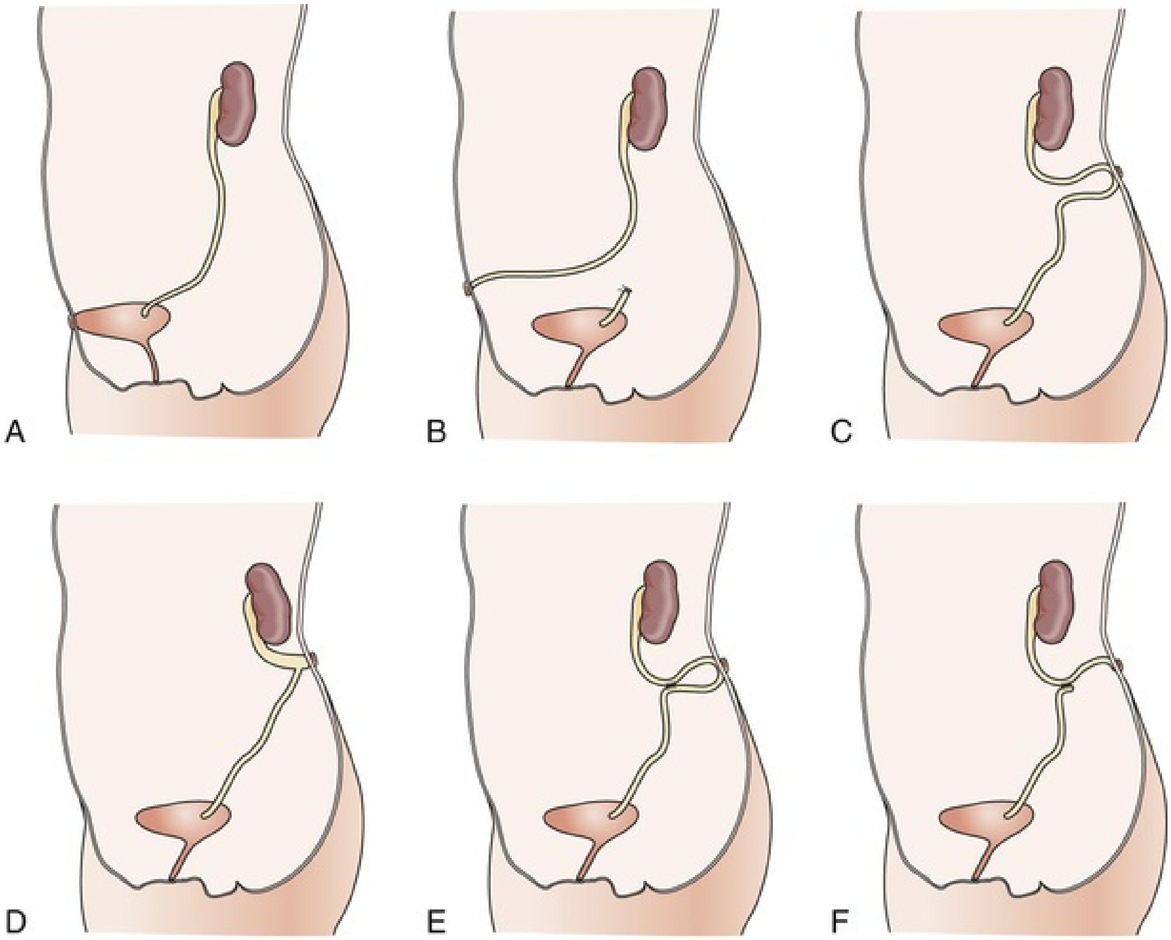

FIG. 33.14 The variety of urinary tract diversions useful in posterior urethral valves. (A) Vesicostomy. (B) Distal ureterostomy. (C) Proximal loop ureterostomy. (D) Cutaneous pyelostomy. (E) Ring ureterostomy. (F) Sober Y ureterostomy. (From Glassberg KI, Horowitz M. Urethral valves and other anomalies of the male urethra. In: Belman AB, King LR, Kramer SA, eds. *Clinical pediatric urology.* 4th ed. London: Martin Dunitz; 2002:899–945.)

Contemporary studies and long-term follow-up of these patients, however, failed to detect long-term renal protective benefit of high diversion, and necessarily require an often complicated undiversion procedure as the child matures (Smith et al., 1996). Moreover, the finding that renal biopsies taken at the time of high urinary diversion uniformly show renal dysplasia, while the diversion does not seem to protect from renal failure, suggests that renal dysplasia occurring in early fetal development is the primary mediator of renal outcome, rather than any type of complex surgical undertaking in the neonate (Tietjen et al. 1997).

Upper urinary tract diversion is a rare undertaking in an infant with complete decompression of the lower urinary tract but worsening renal function, increasing upper tract dilation, and, possibly, a clinical picture of sepsis. Diversion would be considered with the clear understanding that any expectation of improved renal outcome is not borne out by available evidence. A complex secondary surgery will be required, and the bladder may be exposed to a potentially extended period of defunctionalization with attendant risks of impairment in compliance and contractility (Close et al., 1997). The preferred initial surgical intervention for infants with PUVs should be considered endoscopic valve ablation, followed by a properly constructed vesicostomy when primary valve ablation is impossible or bladder decompression is not achieved by urethral catherization or valve ablation alone. In the unique case in which upper tract dilation persists after vesicostomy and is accompanied by worsening renal parameters, upper urinary tract diversion with a cutaneous ureterostomy or renal pyelostomy is considered after multispecialty consultation with pediatric nephrologists and radiologists.

Circumcision

A urinary tract infection can quickly progress to pyelonephritis and sepsis in an infant with PUVs caused by the associated morbidities of vesicoureteral reflux, incomplete bladder emptying, and severe upper urinary tract dilation. **The overall risk for urinary tract infection in children with PUVs is 50% to 60%**

—several magnitudes greater than the 1% risk for unaffected boys (Mukherjee et al., 2009; Bader and McCarthy, 2013). **Circumcision reduces this risk for urinary tract infection by 83% to 92%, a risk reduction similar to that for uncircumcised boys** (Wiswell et al., 1988; Mukherjee et al., 2009). It is recommended that a circumcision be strongly considered as a prophylactic measure for any boy diagnosed with PUVs and should certainly be completed before giving any consideration to a ureteral reimplant in a scenario of frequent febrile urinary tract infections despite conservative measures.

Nephroureterectomy

Nephroureterectomy was historically considered an appropriate intervention for valve patients manifesting elements of the VURD syndrome discussed previously. The nonfunctioning renal unit in association with dilating urinary reflux was long considered a potential source for infection and sepsis, and prophylactic excision was considered appropriate. In contemporary practice, a focus on proper bladder emptying and circumcision has decreased the incidence of urinary tract infections sufficiently that nephroureterectomy is rarely considered. Indeed, renal preservation for even poorly functioning renal units contributing moderate polyuria are easier to manage than anuria**. If frequent urinary tract infections localizing to the nonfunctioning renal unit necessitate a nephrectomy, preserving the ureter for potential subsequent reconstruction, such as a ureteral augmentation, is recommended** (Husmann et al., 2004).

Key Points

- Cystoscopy with valve ablation is the preferred initial treatment for PUVs.
- Vesicostomy does not inhibit bladder cycling, as the bladder continues to contract, but is reserved for select cases in which valve ablation is not possible.
- High urinary diversion offers no renal protective benefit and requires a complex secondary procedure to reverse the diversion.
- Circumcision should be encouraged as a prophylactic measure for any boy with PUVs, and especially any boy with a history of urinary tract infection.

Management of Vesicoureteral Reflux

A voiding cystourethrogram will reveal vesicoureteral reflux (see Fig. 33.9) in 50% to 80% of infants undergoing a workup for PUVs (Puri and Kumar, 1996; Tourchi et al., 2014). As discussed in the previous section, infants with valves are also at an increased risk for urinary tract infections, and the co-existence of reflux and valves presents a clinical scenario that may suggest a role for ureteral reimplantation. However**, it is important to understand that reflux in these infants is a consequence of obstruction and that the secondarily elevated bladder pressures are critical to management and should dissuade a ureteral reimplantation in nearly all cases.** Indeed, ablation of the valves or vesicostomy alone will resolve ureteral reflux in 25% to 40% of patients with urinary reflux before ablation (Hassan et al., 2003; Tourchi et al., 2014).

Reflux resolves more readily in lower grades of reflux and also when associated with a kidney with adequate renal function. Hassan et al. found that the presence of urinary reflux did not correlate with renal outcomes, underscoring that the presence of reflux alone should not be seen as an indication for intervention (Hassan et al., 2003). All efforts in a symptomatic valve patient with vesicoureteral reflux must focus on addressing any persistent bladder outlet obstruction, reducing intravesical pressures by considering anticholinergic treatment, and treating underlying bladder dysfunction that is common in bladders exposed to fetal bladder outlet obstruction. Urodynamic evaluation may help guide management in this regard (Kim et al., 1997).

In the rare event that a clinical scenario of recurrent urinary tract infections mandates intervention in a child with PUVs, bladder management in advance of intervention is a critical component in ensuring favorable surgical outcomes (Hunziker et al., 2012).

Surgical correction is considered recognizing also the higher complication rate of stricture and persistent reflux associated with reimplanting dilated ureters into thick-walled bladders that are not properly rehabilitated before surgery (Coleman and McGovern, 1978; Atwell, 1983). Indeed, any treatment of urinary reflux in a child with profound bowel dysfunction potentially puts an already compromised renal unit at risk for further deterioration (Sillen et al., 2010; Tekgul et al., 2012). Endoscopic correction of reflux seems to carry less of the risks of myogenic disruption and renal deterioration seen with ureteroneocystotomy in children with valves, but the overall surgical success rate is lower than that for children without valves (Puri and Kumar, 1996; Tourchi et al., 2014).

Bladder Dysfunction and Valve Bladder Syndrome

Consequent to exposure to obstruction from its earliest development, the bladder is necessarily the focus of management and rehabilitation throughout the life of a boy diagnosed with PUVs (Parkhouse et al., 1988). **The extent of remodeling and subsequent functional compromise may vary, but the bladder and its dysfunction begins a cascade of pathophysiologic changes including voiding dysfunction, urinary reflux, and worsening of renal dysplasia and obstructive uropathy. The ultimate manifestation of this dysfunction is the valve bladder syndrome.**

Urodynamics plays an important role in monitoring an affected child's progression through various well-described changes in bladder function throughout childhood. **The bladder evolves through three distinct contractility patterns throughout childhood: (1) detrusor hyperreflexia in infancy and early childhood; (2) decreasing intravesical pressures and improved compliance bladder in childhood; and (3) increased capacity bladder with hypocontractility and atony in adolescence** (Peters et al., 1990; De Gennaro et al., 2000). Holmdahl et al. stressed that the pattern outlined here overlaps in most children, emphasizing that the patterns described earlier are not arbitrary or destined to happen, but rather useful guideposts in monitoring and helpful in offering management solutions and assessing the effectiveness of intervention over the long-term (Holmdahl et al., 1995).

Mitchell conceptualizes a vicious circle in voiding dysfunction in which the outlet obstruction begins a cascade of events leading to the end-stage bladder, or valve bladder. Bladder outlet obstruction leads to detrusor hypertrophy, which increases the voiding pressures initially as the bladder strives to complete emptying. As further remodeling of the bladder occurs, however, the PVR begins to increase as the urine output increases. Ultimately, the bladder cannot meet the demand of emptying and the detrusor decompensates. This is not to state that the devolution to a valve bladder is unavoidable nor uniformly applicable and expected. One may hypothesize that active, appropriate intervention to effectively drain the overdistended bladder could alter the course toward decompensation and preserve bladder functionality.

Boys with PUVs were noted to achieve daytime and nighttime continence later than peers without this issue (5.5 years vs. 2.9 years; Jalkanen et al., 2016). Bladder dysfunction, even when not detected on clinical history alone, must always be suspected in children with a history of valve ablation. One systematic review of 34 studies describing renal function, vesicoureteral reflux, and urodynamic findings after endoscopic valve ablation in 1474 patients found that although the self-reported history of incontinence ranged widely between 0% and 70%, the mean incidence was 19%. But when urodynamic outcomes were examined, the incidence of bladder dysfunction rose to a mean of 55% (Hennus et al., 2012). **Reliance on clinical examination or patient questionnaires alone may grossly underestimate bladder dysfunction, and obtaining a uroflow and checking PVRs should be a routine part of follow-up in toilet-trained children with a history of PUVs** (Lopez Pereira et al., 2013).

Bladder Management

The typical follow-up for children with valves after ablation for bladder dysfunction has focused on observation, clinical history, and urodynamics. Education of parents and growing children is a critical component of bladder management and success of any prescribed behavioral modifications**. Families are counseled to not aggressively push an affected child toward toilet training and to expect a lag compared with the normal population. Daytime incontinence is not uncommon, ranging from 7% to 35%, and nocturnal enuresis is expected in 1 of 4 children with a history of valve ablation** (Hennus et al., 2012). **Once toilet training is achieved, children and caregivers are educated to ensure adequate fluid intake, void on a timed regimen, and practice double-voiding. Biofeedback therapy and home pelvic floor exercises have also shown to be useful** (Ansari et al., 2008).

The role of adjunctive medications is unclear. The preferred intervention is predicated also on varying proposed etiologies of voiding dysfunction after valve ablation: (1) functional obstruction at the bladder neck caused by hypertrophy or (2) bladder wall thickening caused by detrusor wall thickening from increased collagen deposition. One study suggests the use of α-adrenergic blockade to relieve sphincteric hypertonicity and relax the bladder neck in children with high PVRs, finding a significant reduction in residual volumes (Abraham et al., 2009). In contrast, Casey et al. administered oxybutynin at 0.1 mg/kg twice daily in 18 consecutive infants undergoing urodynamics at 3 months post–valve ablation, showing high voiding pressures or small bladder capacity (Casey et al., 2012). Although the study found that both parameters improved significantly with oxybutynin, the lack of a control group in both studies and the fact that detrusor hypercontractility and elevated voiding pressures are a normal finding in neonates necessitate more rigorous, prospective studies (Sillen et al., 1992; Casey et al., 2012). If oxybutynin is chosen, its use must be closely monitored for effect, and if a growing child begins to demonstrate higher bladder residual volumes and capacity, oxybutynin should be stopped. Therapy was ceased in 4 of 18 patients in the Casey et al. study, and another found that myogenic failure required clean intermittent catheterization (CIC; Kim et al., 1997; Casey et al., 2012). It is unclear whether the myogenic failure was a consequence of evolving bladder dysfunction inherent to PUVs or secondary to oxybutynin, but caution, nevertheless, should be exercised during the treatment period.

Role of Urodynamics

As outlined earlier, bladder contractility changes as the child ages and must be considered a dynamic condition. The clinician must carefully monitor the bladder function of a child affected by PUVs, and urodynamics is an important modality to facilitate this goal. Combining fluoroscopy to standard urodynamics, or videourodynamics, is especially useful in properly assessing storage and emptying in dynamic conditions, and in offering an understanding of the contribution of vesicoureteral reflux to bladder function (Fig. 33.15AB). Urodynamics may be most useful when there is a change in the clinical scenario, such as worsening upper tract dilation or presence of urinary tract infections. Yet, any putative benefit of videourodynamics must be understood in the context of known disadvantages of radiation exposure and infection (Concodora et al., 2017).

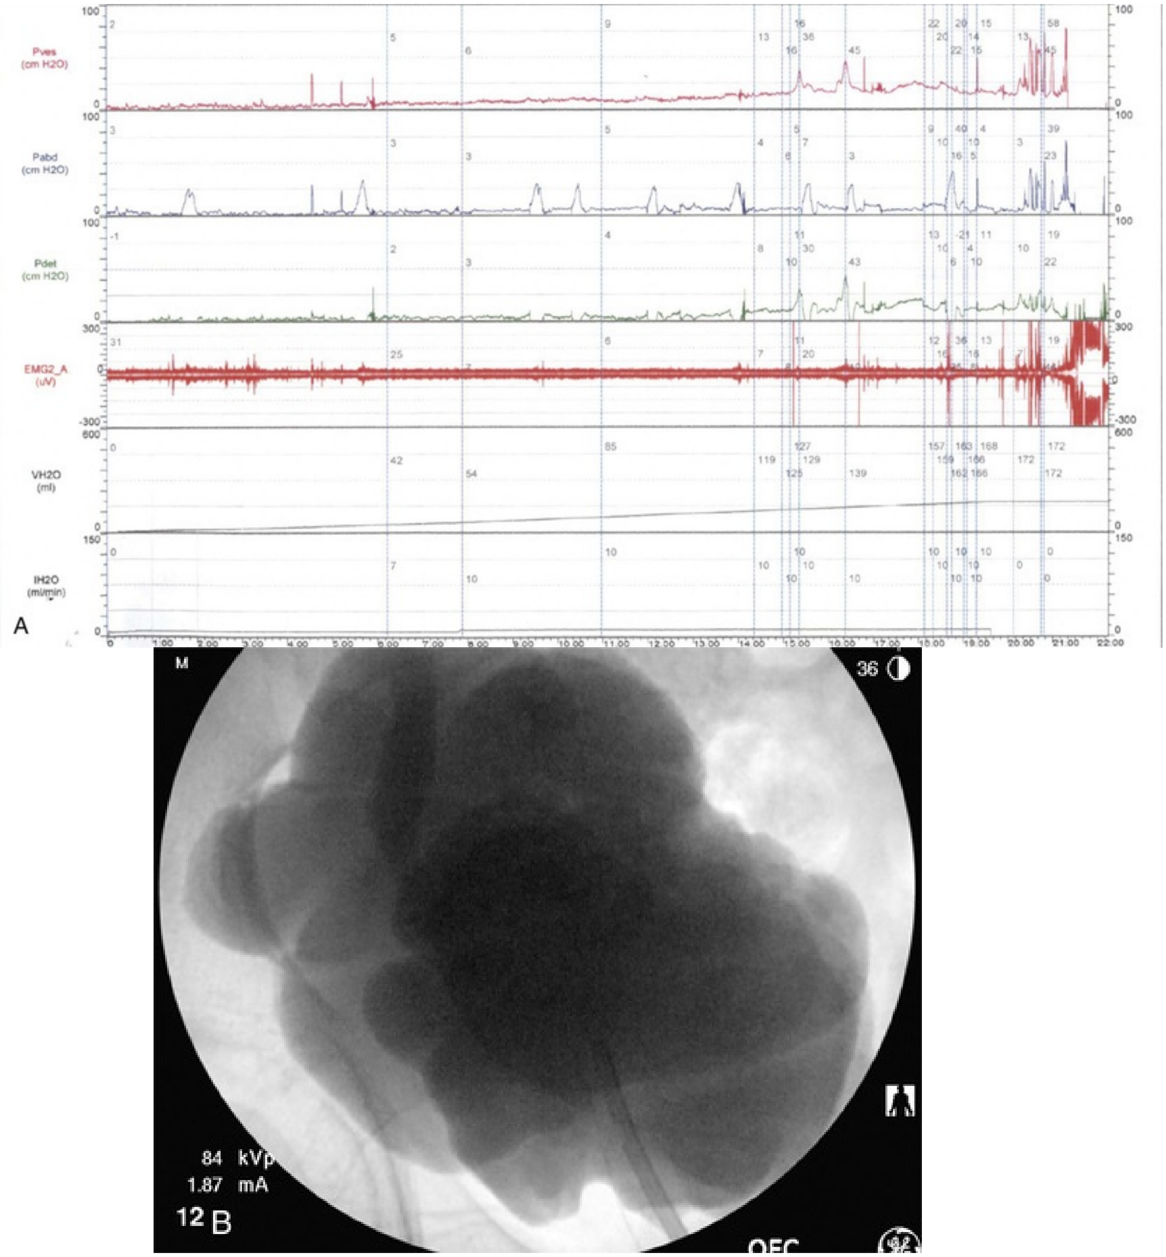

FIG. 33.15 The valve bladder "vicious cycle" illustrated. An affected bladder will lead to increasing postvoid residuals. The sustained stretch will cause increasing collagen deposition and other changes that cause increased pressures being transmitted to the renal pelvis. Subsequent renal tubular injury causes polyuria and increased volume in the bladder that already empties poorly, and the cycle continues leading to additive damage. (A) Urodynamic tracing obtained in 7-year-old boy with a history of posterior urethral valves shows a bladder with preserved compliance, frequent uninhibited contractions, and poor contractility. (B) Fluroscopic image of the same patient during videourodyamics demonstrates a severely trabeculated bladder with right-sided vesicoureteral reflux.

Valve Bladder Syndrome

The term “valve bladder syndrome” was coined by Mitchell in 1982 after reviewing his experience with 11 patients in whom hydroureteronephrosis and renal function continued to worsen despite no clinical evidence of residual bladder outlet. **Mitchell's concept, which is illustrated in Fig. 33.15 and described earlier, holds that although the bladder initially compensates for outlet obstruction by generating high voiding pressures, it begins to experience higher volumes of urine caused by increasing urine production as the child grows. The polyuria caused by nephrogenic diabetes insipidus secondary to evolving renal impairment augments the urine volumes entering a bladder that is increasingly unable to empty completely. As the PVRs increase, the bladder no longer enjoys periods of complete relaxation, and the detrusor fibers are continuously in a state of partial or complete stretch, beginning a cascade of genotypic and phenotypic changes that further impair contractility of the bladder** (Kirsch et al., 2003; Hutcheson et al., 2004; Shukla et al., 2004). And when the bladder does empty partially, the urine already stored in the hydronephrotic kidneys quickly empties into the bladder, once again denying the detrusor muscle periods of relaxation. The impaired contractility and increasing PVRs then transmit the increasing bladder pressures to the kidneys, potentially worsening the already impaired renal function.

In sum then, **there are three processes that contribute toward the devolution of a bladder into a valve bladder:** (1) polyuria; (2) bladder insensitivity; and (3) residual urine volume. These three factors—all secondary to the original insult of impaired bladder compliance creating high wall tension caused by increases in collagen and matrix—conspire to sustain bladder overdistension that ultimately leads to the valve bladder (Koff et al., 2002). Although the goal of intensive management of bladder dysfunction is to arrest the progression toward full expression of late-term manifestations of valve bladder syndrome, *valve bladder syndrome* is actually a broad term describing a continuum of symptoms of bladder dysfunction. As described in the previous section, monitoring urine PVRs, flow rates, and voiding pressures, along with timed voiding, double voiding, and anticholinergics or α-blockers compose the mainstay of treatment. CIC becomes necessary if residual volume increases despite initial interventions with anticholinergics to deter the progression toward decompensation.

Overnight bladder drainage is an important adjunct in therapy and is increasingly adopted as a standard intervention in children with classic evidence of developing a valve bladder syndrome (Koff et al., 2002; Nguyen et al., 2005). Nocturnal bladder drainage is instituted if ureteral dilation and hydronephrosis does not respond to behavioral modification or an affected child develops worsening renal function or recurrent urinary tract infections. The continuous bladder drainage, achieved by leaving a urinary catheter in the bladder over a 7- to 10-hour period, allows an extended period of bladder decompression, even as the kidneys empty urine without encountering the increased voiding or resting bladder pressures they face during the day. This simple step interrupts the “vicious cycle” of bladder remodeling and consequent renal effects caused by chronic bladder distension. Koff et al. and Nguyen et al. noted significant improvements in hydronephrosis, continence, and urinary tract infections after instituting overnight bladder drainage (Koff et al., 2002; Nguyen et al., 2005).

When CIC or overnight bladder drainage is difficult because of an elevated bladder neck or sensate urethra, an appendicovesicostomy utilizing the Mitrofanoff principle presents a useful option (Mitrofanoff, 1980). King et al. followed 24 patients with a valve bladder who underwent the Mitrofanoff procedure to enable CIC for a median of 6.2 years. The study demonstrated that pelvicaliectasis decreased and bladder compliance improved, although renal deterioration still developed in 35% of cases (King et al., 2014).

Minimally invasive approaches to create this catheterizable channel, utilizing both laparoscopic and robotic assisted approaches, are increasingly being adopted at many centers (Mitrofanoff 1980; Hsu and Shortliffe, 2004; Nguyen et al., 2009; Famakinwa and Gundeti, 2013; Famakinwa et al., 2013) (Fig. 33.16A–C). A large, multi-institutional review of the robotic-assisted laparoscopic Mitrofanoff procedure confirmed its safety with a revision rate of 12.5% (Famakinwa and Gundeti, 2013) The robotic-assisted approach potentially limits the field of dissection and could, in older children, make it difficult to mobilize the appendix and perform bladder mobilization with anastomosis of the appendix through a single robot docking. In such situations, a pure laparoscopic approach could be used to mobilize the appendix, followed by docking of the robot with standard triangulation of port sites focused on the pelvic midline for anastomosis of the appendix.

FIG. 33.16 Robot-assisted laparoscopic appendicovesicostomy in a child with valve bladder syndrome and a history of posterior urethral valves. (A)

The detrusor muscle is incised in the posterior bladder wall to allow tunneled anastomosis of the appendix. (B) Anastomosis of the appendix to the bladder with a feeding tube traversing the appendix into a cystotomy along the posterior wall of the bladder. (C) Postoperative appearance with appendicovesicostomy stoma visible just inside the umbilicus.

Augmentation cystoplasty is rarely utilized for a valve bladder in the contemporary era, perhaps as a result of improved understanding of bladder dysfunction, behavior modification, and timely institution of overnight bladder drainage. But when faced with a small-capacity, high-pressure, and thick-walled valve bladder with worsening upper tract anatomy refractory to conservative measures, augmentation may be considered. Ureteral augmentation is preferred in children with PUVs as it reduces the risk for mucous production, acidosis, and stones that are common to ileal augmentation. Moreover, severe ureteral dilation or unilateral VURD seen in boys with valves offers an ideal clinical scenario where the ureter can be detubularized and patched on a bisected bladder without bowel manipulation. Johal et al. reported lasting benefits of increased capacity and decreased filling pressures at a mean follow-up of 4.5 years after ureteral augmentation (Johal et al., 2008).

Key Points

- The focus of management for vesicoureteric reflux in a child with valves should be centered on the bladder, and ureteral reimplantation is rarely offered.
- The bladder evolves through three patterns in boys with valves: (1) detrusor hyperreflexia in infancy and early childhood; (2) decreasing intravesical pressures and improved compliance bladder in childhood; and (3) increased capacity bladder with hypocontractility and atony in adolescence.
- Videourodynamics is completed in boys with valves especially when there is a clinical change: increasing upper tract dilation or recurrent urinary tract infections.
- Overnight bladder drainage is considered in the scenario of increasing PVRs, urinary tract infection, or worsening hydronephrosis and renal function.

Prognostic Indicators for Renal Function

Despite numerous advances in antenatal diagnosis and intervention and rapid postnatal evaluation and treatment, the lifetime prevalence of end-stage renal disease in boys with PUVs is between 20% to 50% (Parkhouse et al., 1988, Smith et al., 1996; Sarhan et al., 2011). Risk factors known to affect the prognosis of an infant diagnosed with PUVs include age at diagnosis, renal dysplasia with or without vesicoureteral reflux, nadir creatinine during 1 year of life, recurrent urinary tract infections, and bladder dysfunction.

Nadir creatinine has long been considered a relatively easy method of predicting long-term renal outcome in affected children. The nadir creatinine value measured at 1 year of life appears to be more accurate as a predictive tool than the value obtained at 1 month of age (Drozdz et al., 1998; Lal et al., 1999; Heikkilä et al., 2011). **A serum creatinine of less than 0.8 mg/dL appears to indicate a minimal risk, and a value greater than 1.2 mg/dL at 1 year of age predicts a higher risk for developing end-stage renal failure** (Drozdz et al., 1998; DeFoor et al., 2008). In those studies suggesting that a 1-month post-treatment serum creatinine is a more accurate predictor of renal function, again, the value of less than 0.8 mg/dL at 1 month after treatment seems to indicate better long-term outcomes (Rittenberg et al., 1988). Coleman et al. concluded that a nadir creatinine at 1 month of greater than 0.85 mg/dL implies a higher risk for renal failure, and values of less than 0.4 mg/dL may be considered lower risk (Coleman et al., 2015a, 2015b). Creatinine velocity (the rate of change of creatinine over time) in the first 30 days of life has also been postulated to be a predictor of renal failure (Coleman et al., 2015a, 2015b).

Age at presentation remains an unclear predictor of future renal outcomes. The assumption that antenatal diagnosis would lead to more rapid diagnosis of PUVs and, therefore, forestall renal injury has not been sustained. Indeed, Heikkilä et al. found that patients diagnosed in the presonography era before 1982 had a risk for end-stage renal disease of 16.8%, as compared with 36.6% developing renal failure if diagnosed during the postsonography era (Heikkilä et al., 2011). Another review found a similar variation, with 41% of those presenting before 1 year of age having poor long-term renal outcome compared with 15% of those presenting after 1 year of age (Parkhouse et al., 1988). This difference in outcomes may be explained by the assumption that the critically ill infants in the presonography era likely died before diagnosis was complete, and early interventions, including fetal measures in the current era increased survival dramatically. These infants born after 1982, then, may previously have died and tended to have more severe manifestations of valve disease and related comorbidities contributing to poorer renal outcomes.

Another common assumption, not corroborated, was that the later presenting children likely had a milder variant of valve disease, allowing them to go undetected for some years before presenting with more vague symptoms of voiding dysfunction. But some reports found much poorer outcomes in children presenting outside of the neonatal period with PUVs, with delayed presentation associated with a significantly higher risk for azotemia, higher serum creatinine, and poorer long-term renal outcomes (El-Sherbiny et al., 2002; Ziylan et al., 2006; Sarhan et al., 2011).

Quantifying renal dysplasia without a renal biopsy requires reliance on available imaging technology including renal sonography and nuclear scintigraphy. Hyperechogenic kidneys, cystic changes in the cortex, and loss of corticomedullary differentiation are considered to portend a poor prognosis (Robyr et al., 2005). Pulido et al. examined the association of the renal parenchymal area—defined as the area of the kidney minus the area of the pelvicalyceal system on the first postnatal ultrasound—with end-stage renal disease. Reviewing the first postnatal ultrasound images of 60 patients followed for 393 person-years, the authors found that for infants with a 1-month-of-life serum creatinine between 0.8 mg/dL and 1.1 mg/dL, each 1-cm^2 increase in renal parenchymal area was associated with a lower risk for end-stage renal disease (Pulido et al., 2013). Odeh et al. concluded that there is a significant difference in parenchymal area between children who proceed to renal failure versus those who do not (21.41 cm^2 vs. 16 cm^2), along with a difference in the corticomedullary differentiation index (Odeh et al., 2016). Recently, fetal MRI (Faure et al., 2017), postnatal ultrasound findings (Hochart et al., 2016), and genetic markers (Faure et al., 2016) have been used to predict risk for renal deterioration. These studies highlight the need for novel ways of predicting renal outcomes in children with valves and certainly more definitive and powerful predictive tools that incorporate genetic and biochemical markers (Farrugia et al., 2006).

Transplantation in Valve Patients

The prevalence of end-stage renal disease in boys with a history of end-stage renal disease is up to 50%, and the 2006 annual report of the North American Pediatric Renal Trials and Collaborative Studies listed obstructive uropathy as the second most common cause for transplantation, accounting for 1424 of 8990 transplant cases (15.8%) since 1987 (Smith et al., 2007).

Patients with PUVs receiving renal transplant compose an especially difficult cohort for receiving a renal transplant. These boys are likely to have several comorbidities including high-grade vesicoureteral reflux into native, nonfunctioning kidneys and valve bladder syndrome with a thick-walled, poorly contractile or hypercontractile bladder. A pediatric urologist must be a critical component of the transplant team and should carefully examine the prospective recipient as part of the pretransplant evaluation. Recipients have significantly higher complication rates and graft loss rates in boys in whom bladder dysfunction is incompletely managed or bladder reservoir is not optimized (Sheldon et al., 1994; Mendizabal et al., 2005).

Outcomes after renal transplant in children with PUVs have been mixed. **The thickened bladder wall of PUV patients may contribute to the significantly increased incidence of ureteral obstruction on univariate and multivariate analysis compared with a non–PUV transplant cohort, but recent studies saw no risk for increased graft loss or patient death despite ureteral obstruction, stenting, or dilation** (Indudhara et al., 1998; DeFoor et al., 2003; Smith et al., 2010; Fine et al., 2011). Fine et al. reported on 59 valve patients that underwent renal transplant with 8-year follow-up and found that outcomes were similar whether a boy underwent an initial valve ablation, vesicostomy, or supravesical diversion; and although bladder dysfunction increased the risk for graft failure, the effect did not reach significance (Fine et al., 2011).

Videourodynamics should be obtained for transplant candidates to determine the safe storage pressures and contractile function of the future reservoir. Overnight bladder drainage or CIC may be initiated before transplant to optimize the reservoir and establish proper bladder management skills that will be essential for graft success after transplant. Pretransplant nephrectomy is rarely required and is only considered in cases where proteinuria or severe polyuria is creating hemodynamic challenges.

If augmentation is felt necessary based on unsafe storage pressures in the bladder, this reconstruction can be considered before or after transplantation. Although previous dogma suggested that a pretransplant augmentation is preferable to prevent the undertaking in an immunocompromised child or one too young to take responsibility for catheterization and pouch management, recent experience argues that transplantation into even a vesicostomy is a safe alternative until the child grows to an appropriate age for cystoplasty and the attendant reliance on CIC (Rigamonti et al., 2005; Christman et al., 2013). A recent meta-analysis confirmed this reluctance to proceed with prerenal transplant augmentation cystoplasty, finding that augmentation cystoplasty does increase the risk for urinary tract infection in children with PUVs. The authors also noted that if augmentation cystoplasty is deemed necessary, it can be performed after transplant with surgical outcomes no different from doing it before transplantation (Jesus and Pippi Salle, 2015). Still, Lopez Pereira et al. found that augmentation cystoplasty did not compromise transplant kidneys and that the infection rate is very similar between children who were augmented versus those who were not as long as they are compliant with their catheterization protocol (Lopez Pereira et al., 2014).

Quality of Life With Posterior Urethral Valves

It must be emphasized that PUVs is an illness with lifetime repercussions. Understanding these long-term risk factors and their impact on quality of life is necessary for counseling, preparing, and treating valve patients as they reach adulthood.

The evolution of the valve bladder and the associated comorbidities of renal transplantation that many valve patients face are associated with well-known risks including erectile dysfunction and infertility. The lower urinary tract symptoms that affect children with valves will affect them as adults two to three times more often than in the general population (Tikkinen et al., 2011). A survey of 67 adult patients with valves found that the overall rate of erectile dysfunction or infertility was not different than the general population (Taskinen et al., 2012). But a subgroup analysis of these same patients with urinary incontinence or renal insufficiency showed that valve patients had the greatest evidence of impaired quality of life, underscoring the necessity of long-term follow-up and active treatment well into adulthood (Jalkanen et al., 2013). **Indeed, the chronicity of bladder dysfunction, risk for urinary tract infections, and sequelae of renal dysfunction require communication between pediatric and adult urologists, even as the adult urologist should be knowledgeable of the pathophysiology of PUVs and well prepared to provide care to these patients after their transition into adulthood.**

Key Points

- An antenatal vesicoamniotic shunt can be considered in select patients with bladder wall thickening, hydroureteronephrosis, and oligohydramnios. Although it may reduce the severity of pulmonary hypoplasia, the procedure confers no protection from renal impairment.
- A nadir serum creatinine at 1 year of less than 0.8 mg/dL confers a significantly decreased risk for developing end-stage renal disease.
- Transplantation into a valve-affected bladder may carry a higher risk for

ureteral obstruction, but there is no increased risk for graft loss compared with controls.

Anterior Urethral Valves

Anterior urethral valves are the most common congenital obstructive lesion of the anterior urethra but are 25 to 30 times less common than PUVs (Confer et al., 2010). Because the condition is often found in association with a large anterior urethral diverticulum, the valve itself is varyingly described as an obstruction resulting from a wall of the diverticulum obstructing flow, or a semilunar fold draping down from the wall of the anterior urethra interrupting urinary flow (Tank, 1987; Paulhac et al., 2003). The embryology of anterior urethral valves is not clear, but hypoplastic corpus spongiosum over the affected portion of the anterior urethra indicates a place on the hypospadias spectrum or a faulty union between urethral mucosa and the epithelium of the fossa navicularis. A rupture of dilated bulbourethral glands has also been suggested as an etiology (McLellan et al., 2004). The valves may be located at the bulbar urethra, penoscrotal junction, or penile urethra (Firlit et al., 1978).

Patients present with anterior urethral valves at different ages based on the severity of the obstructive process. **Symptoms may consist of postvoid dribbling and mild incontinence, significant bulging of the distal penis, palpable bladder with obstruction, or even renal insufficiency and urinary tract infections** (Cruz-Diaz et al., 2013). Diagnosis requires a careful examination of the external genitalia, and compression of the distal shaft may result in expressing urine as seen in a diverticulum (see Fig. 33.16A). The voiding cystourethrogram is required to confirm the diagnosis and may demonstrate a dilated anterior urethra with proximal signs of chronic obstruction including bladder diverticula and massive vesicoureteral reflux (see Fig. 33.16B).

The treatment approach to anterior urethral valves varies according to age of presentation, extent of upper tract damage, and extent of anterior urethral deformity. In a premature or small infant, a vesicostomy may be required to facilitate relief of obstruction until the infant can accommodate a cystoscope or undergo further reconstruction. **In the majority of cases, cystoscopy with valve ablation using a bugbee electrode or laser is possible as an initial treatment, and when successful, no further surgery of the urethra is required** (Cruz-Diaz et al., 2013). In more severe cases in which a gross urethral diverticulum is seen, **surgical reconstruction over a urethral catheter may be required.**

Up to 80% of children with anterior urethral valves will develop bladder

dysfunction, and bladder instability, hyperreflexia, and diminished compliance and capacity will be seen on urodynamics (Kajiwara et al., 2007). As with PUVs, long-term renal function is contingent on preoperative creatinine and glomerular filtration rate. Routh et al. performed a multivariate analysis of data available from 97 studies including 229 patients with anterior urethral valves and found that pretreatment azotemia, vesicoureteral reflux, and urinary tract infection together increased the risk for poor renal outcome 25-fold (Routh et al., 2010). Still, because of the milder and more subtle presentation, the overall incidence of preserved renal function in anterior urethral valves is better than PUVs, with 78% of patients having normal renal function after treatment (Routh et al., 2010).

Urethral Atresia

Urethral atresia, or the congenital urethral stricture, is a rarely described entity likely caused by its high associated mortality (Fig. 33.17). When an infant survives—because the obstruction is incomplete or because there was decompression caused by an antenatal shunt placement or a patent urachus—the outcome can be similar to a child with obstructing PUVs (Gonzalez et al., 2001). **An obstructing membrane is typically seen at the distal end of the prostatic urethra, and the urethra distal to that point may be hypoplastic. As a part of the LUTO spectrum seen in antenatally detected anomalies of the lower urinary tract, the obstruction is confirmed after birth with cystoscopy, and a vesicostomy is usually required** (Freedman et al., 1999).

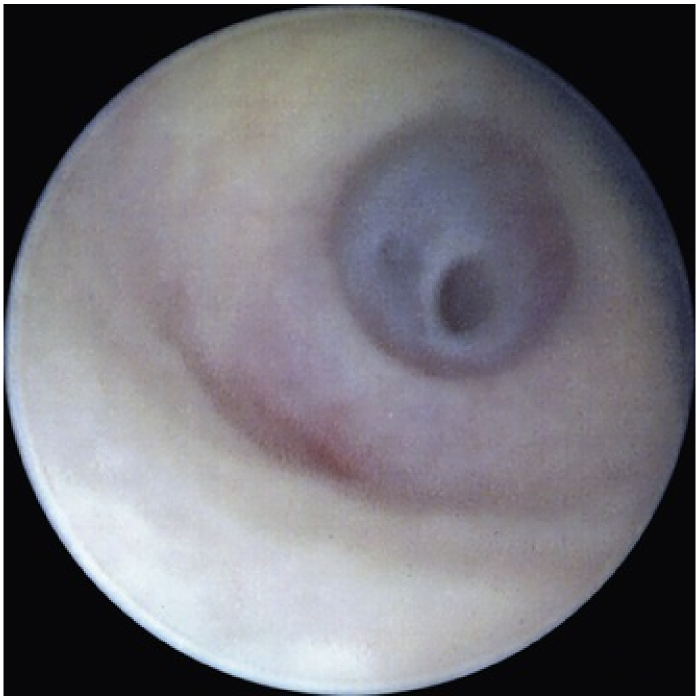

FIG. 33.17 Image obtained during cystoscopy on day 2 of life in a neonate with a prenatal history of lower urinary tract obstruction (LUTO). Cystoscopy demonstrates a near-complete urethral obstruction in the mid-bulbar urethra most consistent with urethral atresia.

Whether urethral atresia is a precipitating factor for development of prune-belly syndrome in certain cases remains controversial, but infants with urethral atresia or congenital urethral stricture often will present with oligohydramnios, bilateral hydroureteronephrosis, and weak abdominal wall musculature. The Progressive Augmentation by Dilation Urethra Anterior (PADUA) initially reported by Firlit, is considered a safe alternative for restoring urethral continuity in select cases without complex reconstructive surgery (Passerini-Glazel et al. 1988), but long-term data is lacking.

Urethral Duplication

Urethral duplication is another rare anomaly of the urethra with several known anatomic variants. The duplication may begin at the bladder neck or within the more distal urethra. **Although one urethra usually terminates on the glans near its orthotopic position, another urethra may end in a meatus placed on the glans or more ventrally along the shaft of the penis. In the most severe cases, the duplicated urethra may even be as proximal as the anal sphincter. The duplication occurs in a sagittal plane, with the ventral urethra, usually the functional meatus, containing the sphincteric complex and verumontanum.**

Effmann et al. are credited with the most widely used classification system for urethral duplications (Effmann et al., 1976) (Fig. 33.18A-J). Broadly, **the type I abnormality includes a blind incomplete urethral duplication or accessory urethra. Type II is a complete patent urethral duplication with four subytpes, and type III refers to urethral duplication as a component of partial or complete caudal duplication.** The “Y” type duplication refers to a type IIA2 type in which the duplicated urethra arises from the first but diverges away to open into a second meatus that opens as ventral as the rectum.

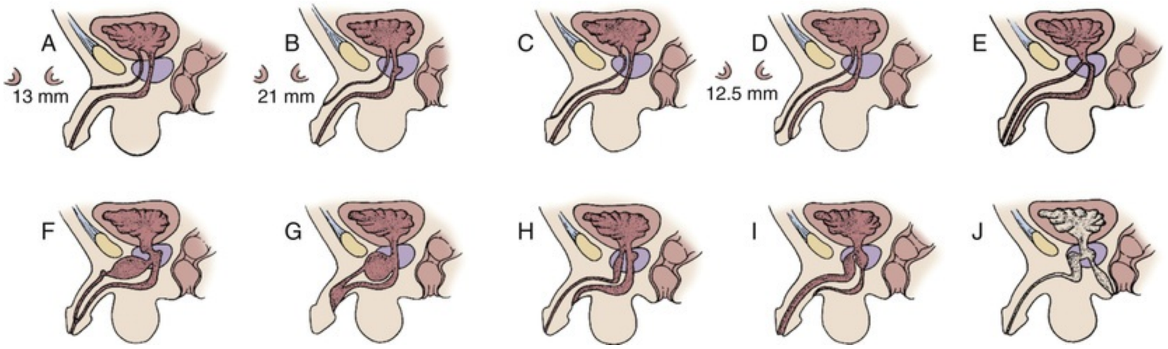

FIG. 33.18 Illustration of different types of urethral diverticulum. (A to J) Variations of urethral duplications shown in the sagittal plane. Each of these drawings illustrate that the ventral urethra is the functional one as it passes through the orthotopic prostate and sphincter.

Diagnosis is readily made in some cases when two distinct meatal openings are seen on the glans, but in other cases requires a high index of suspicion when examining what appears to be an atypical case of proximal hypospadias with a patent appearing opening on the glans. A voiding cystourethrogram will confirm the diagnosis during the voiding phase in many cases, although a retrograde injection of the distinct urethra can also be accomplished (Fig. 33.19AB; Hoekstra and Jones, 1985; Podesta et al., 1998).

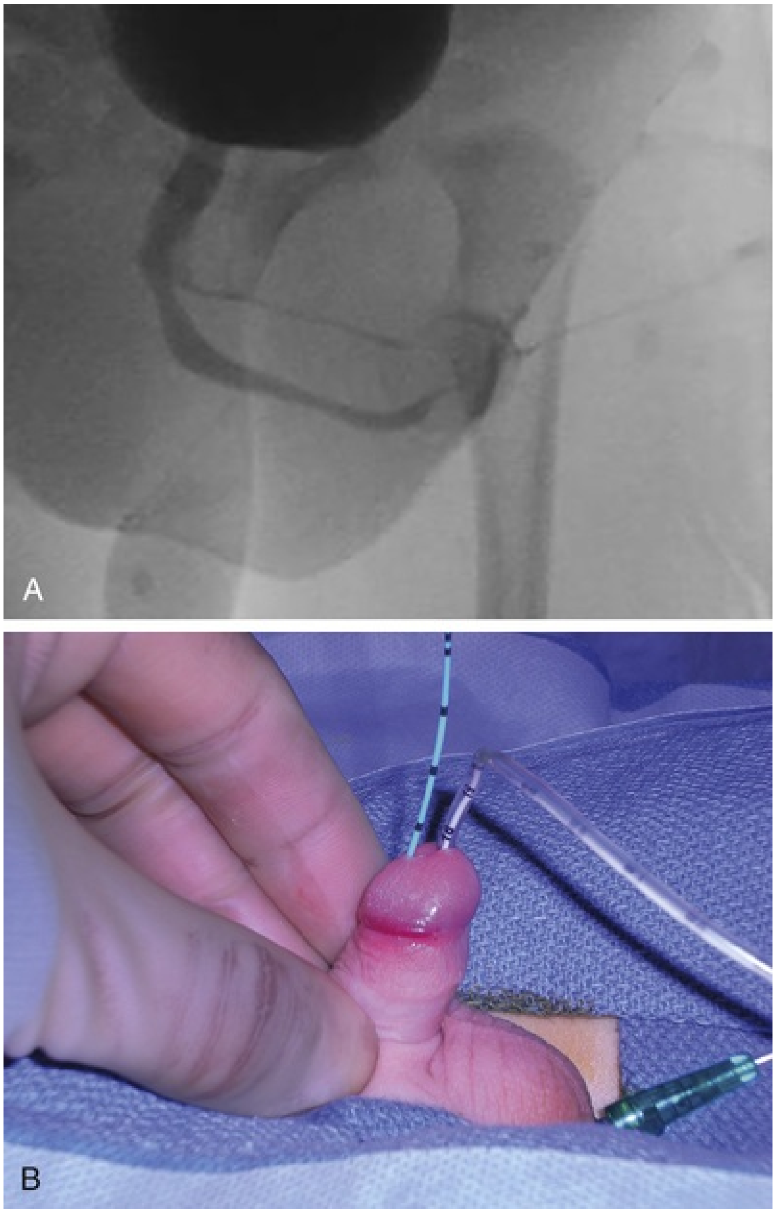

FIG. 33.19 (A) Voiding cystourethrogram in a male child showing urethral duplication. (B) Clinical demonstration of the same child in the operating room with the larger-caliber ventral urethra and the narrower dorsal urethra.

Surgical management is complex and may require a variety of single- or multiple-stage repairs. A small, blind-ending accessory urethra may be conservatively monitored or treated expeditiously with simple coagulation of the mucosal tract with a bugbee electrode. A patent duplicated urethra connected to the bladder with a distinct bladder neck will require a planned reconstruction. When two urethral openings are found on the glans, the more dorsal urethra may mimic the appearance of a distal epispadias. Alanee et al. described a technique by which the septum between the two urethral channels is incised and the dorsal defect is repaired with reverse glans wings to cover a dorsal urethroplasty (Alanee et al., 2012). In cases in which the urethral openings are separated by the “Y”-type arrangement, a staged reconstruction using preputial or buccal mucosa flaps may be required to bring the more ventral but functional meatus to the glans penis, where it can be insinuated into the dorsal, usually atretic, urethra.

The anterior sagittal trans-ano-rectal approach (ASTRA) is another option for select cases as a means to mobilize the ventral, functional meatus placed in the anal sphincter (Macedo et al., 2012). The ventral urethra may be mobilized to bridge the gap with the rest of the urethra reconstructed using preputial skin as reported by Kaye et al. (Kaye et al., 2012) (▶Video 33.2). In our experience, if the distal aspect of the orthotopic, or dorsal, urethra is of sufficient caliber, then the ventral urethra may be mobilized sufficiently enough to be directly anastomosed to the dorsal, orthotopic urethra. It is essential to recognize that treatment strategies vary significantly in cases of duplex urethra, and surgical strategy needs to be devised based on individual anatomy.

Urethrorrhagia

Urethrorrhagia, usually referred to as idiopathic urethrorrhagia, describes a spotting of blood on the underwear after urination or voiding of clear urine followed by a few drops of blood. The visible blood tends to raise alarm within families, but the condition is typically considered a benign and self-limited condition. Urethrorrhagia is most commonly seen in peripubertal boys.

The etiology of urethrorrhagia is unclear, although various hypotheses have been offered. Meatal stenosis and dysfunctional elimination syndrome have been suggested as inciting factors (Herz et al., 2005). Proponents of voiding dysfunction as the etiology of urethrorrhagia hold that increased voiding pressures caused by incomplete relaxation of the external urethral sphincter leads to turbulent flow that creates a negative intraluminal urethral pressure. That negative pressure causes an engorgement of the sinuses of the urethral mucosa and small extravasation of blood (Docimo et al., 1998; Herz et al., 2005). Meatal stenosis is similarly proposed as a cause of increased voiding pressures.

Adult urologists consider cystoscopy and upper urinary tract evaluation a necessary step for the evaluation of hematuria, **but the high rate of spontaneous resolution of urethrorrhagia in symptomatic adolescent males —up to 92%—means that routine cystoscopy is not necessary.** Rather, evaluation should focus on a detailed history of bowel and bladder function, renal and bladder ultrasound, and an office evaluation of urinary flow rate and PVRs. If urethrorrhagia becomes atypical—accompanied by symptoms of urethral stricture or increased urethral bleeding—then cystoscopy should be performed.

Although the majority of cases of urethrorrhagia will have an idiopathic origin, urethral strictures are diagnosed after or during evaluation in 14% to 28% of patients presenting with urethrorrhagia (Dewan and Wilson, 1996; Poch et al., 2007). This strong association has led to some debate as to whether cystoscopy itself, in traversing abnormal, inflamed epithelium, initiates stricture formation. Poch et al., in a review of 66 boys with urethrorrhagia, found that cystoscopy in atypical cases of urethrorrhagia identified varying levels of bulbar urethral inflammation, with 24% of patients having a white membranous exudate noted at cystoscopy subsequently diagnosed with a urethral stricture over a mean of 5 years (Poch et al., 2007). In the same cohort, 12% had a stricture found on cystoscopy without any prior history of instrumentation. These findings seem to support a perspective that although cystoscopy is benign in most cases, the procedure may exacerbate the inflammation of an already inflamed urethra in a small population that cannot readily be distinguished by any radiologic modality. A careful analysis of voiding habits and baseline uroflow is, therefore, imperative before cystoscopy is considered (Poch et al., 2007).

Urinary Fistula in Boys With Anorectal Malformation

The vast majority of boys born with an anorectal malformation will have a fistula to the urinary tract (Hong et al., 1992; Fig. 33.20). **Because the initial diverting colostomy is completed during the neonatal period, the fistula tract is usually seen on distal colostogram during subsequent workup before anorectoplasty.**

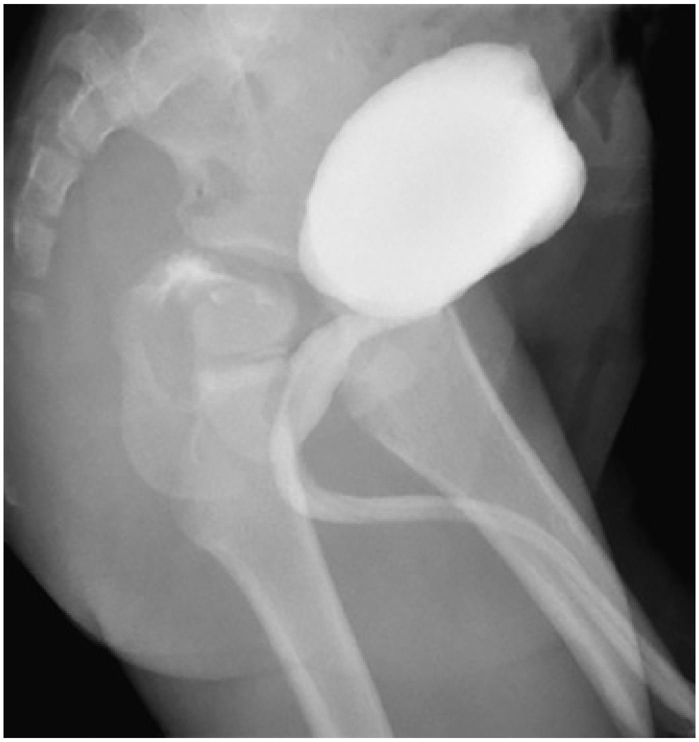

FIG. 33.20 Voiding cystourethrogram in a male infant with an anorectal malformation demonstrates passage of contrast into the rectum via a patent, although small, urethrorectal fistula visualized on the voiding phase of the study.

Pediatric urologists are an integral part of any multidisciplinary team caring for children with anorectal malformations. **Because associated genitourinary anomalies range from 25% to 50%, routine diagnostic imaging to determine the presence of renal anomalies and vesicoureteral reflux is recommended** (Hoekstrar et al., 1983). In an analysis of 190 patients with anorectal malformations, 31 (16.3%) developed a febrile urinary tract infection, of whom 51.6% had a diagnosis of vesicoureteral reflux. On multivariate analysis, the presence of genitourinary malformations was associated with a urinary tract infection, but the association did not reach statistical significance (Sanchez et al., 2014).

When definitive surgical repair is planned in association with general pediatric surgeons, a posterior sagittal approach is preferred to address the rectourinary fistula concurrently. Care must be taken to properly identify the fistula tract and ensure that the tract is excised in its entirety adjacent to the urethra and the rectum to prevent a diverticulum.

A urologist is present at the time of anorectoplasty and fistula repair, and the procedure begins with cystoscopy with an attempt to pass an open-ended ureteral catheter through the fistula tract. A guidewire may also be passed if the caliber of the fistula is small. A urethral catheter is then placed into the bladder, across the urethra. Once the child is placed prone and posterior sagittal anorectoplasty begins, the rectum is adequately mobilized away from the urethra using the previously placed catheter as a guide to location. The fistula tract is excised completely, and the urethral defect is approximated as close to the urethra as possible, reducing the risk for a urethral diverticulum. The rectal defect may be closed primarily, but if redundant intestinal tissue is available, then the fistulous portion of intestine is excised. Healthy adjacent tissue is interposed, and the catheter is left in place for at least 1 week to ensure healing of the urethroplasty.

Key Points

- Anterior urethral valves and urethral atresia are less common causes of LUTO, and long-term outcomes can be similar to those of PUVs if the neonate survives.
- Dysfunctional voiding causing a turbulent urinary flow may lead to urethrorrhagia.
- Treatment for urethrorrhagia should focus on improving voiding habits and conservative management, reserving cystoscopy for refractory cases and when there is significant straining during voiding.
- An infant diagnosed with anorectal malformation should undergo a renal ultrasound and a voiding cystourethrogram because of the high risk for

associated genitourinary anomalies.

Neuromuscular Dysfunction of the Lower Urinary Tract in Children

Carlos R. Estrada MD, MBA, Stuart B. Bauer MD

Neuromuscular dysfunction of the lower urinary tract (LUT) may be either congenital or acquired. The most common cause of congenital dysfunction encountered by the urologist is the condition of neural tube defect (NTD) (Table 34.1). Before 1960, the outcome of children with NTDs was poor, with less than 10% surviving infancy (Rinck et al., 1989). Advances in neurosurgical and urologic care have resulted in a significant improvement in the survival rate such that in the mid-1990s, more than 85% of children survived infancy (Rinck et al., 1989). The most important intervention in this population was the institution of clean intermittent catheterization (CIC) for the prevention of upper urinary tract deterioration (Lapides et al., 1971). A longitudinal cohort study reveals that one-third of children will die before 5 years of age, and a further one-fourth die before 40 years of age (Oakeshott et al., 2010). The risk for death correlates with a higher level of neurologic deficit (Oakeshott et al., 2010). As these patients live longer, renal failure becomes an important cause of mortality, and thus lifelong monitoring and management of the urinary tract is necessary from infancy onward (McDonnell and McCann, 2000; Mitchell, 2005; Singhal and Mathew, 1999). For those children that survive, challenges persist for the achievement of bowel and bladder continence (Bomalaski et al., 1995; Metcalfe et al., 2011) and satisfactory sexual function (Lassmann et al., 2007).

Anorectal malformations		

Neural Tube Defects

Epidemiology of Neural Tube Defects

The most common cause of neurogenic bladder dysfunction in children is abnormal development of the spinal canal and consequently, the enveloped spinal cord. See Fig. 34.1 for an example of an open myelomeningocele. Formation of the spinal cord and vertebral column begins at about the 18th day of gestation. Closure of the canal proceeds in a caudal direction from the cephalad end and is complete by 35 days. The exact mechanism that results in closure and what produces a dysraphic state are yet to be elucidated, but numerous causative factors have been implicated. NTDs have a worldwide incidence of 0.3 to 4.5 per 1000 births (de Jong et al., 2008). In the United States, the birth prevalence of spina bifida has plateaued at approximately 30 per 100,000 (Snow-Lisy et al., 2015). Non-Hispanic white children have a risk of 3.22 per 10,000 births. The risk for children of non-Hispanic black or African-American descent is the lowest at 2.64 per 10,000 births (Boulet et al., 2008). There is geographic and temporal variation in the incidence of NTDs (Olney and Mulinare, 1998, 2002).

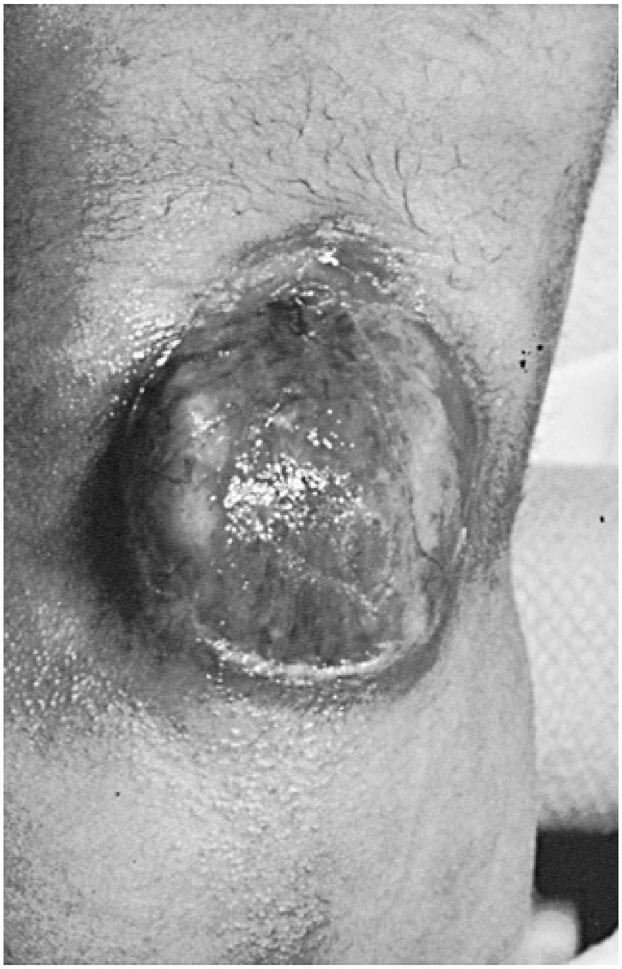

FIG. 34.1 Typical appearance of an open myelomeningocele in a neonate.

Women with low levels of folic acid and impairment of folate-mediated pathways or antibodies to folate are known to be at increased risk for NTDs (Botto and Mulinare, 1999). Folic acid supplementation in prospective randomized trials resulted in a 50% to 70% decrease in the prevalence of NTDs (Botto and Mulinare, 1999; Czeizel and Dudás, 1992; MRC Vitamin Study Research Group, 1991). In 1992, the U.S. Public Health Service recommended that women of childbearing age take a folic acid supplement (400 mcg daily) (MMWR, 1992) because the neural tube develops early in gestation, before most women realize that they are pregnant (Botto and Mulinare, 1999). Thus, it is suggested that the optimal time for folic acid supplementation is at least 4 weeks before and during the first month of pregnancy (Czeizel and Dudás, 1992; Dawson et al., 2001). However, only one-third of women take a folic acid supplement as recommended (Honein et al., 2001). Therefore, governments regulated the fortification of flour and pasta with folic acid in the late 1990s

(Food and Drug Regulations, 1998). Fortification of grains with folic acid has resulted in a 20% to 50% decrease in the prevalence of NTDs (Godwin et al., 2008; Honein et al., 2001).

Risk Factors for the Development of Neural Tube Defects

There is a strong familial risk for neural tube defects. A mother with one affected child has a 20 to 50 times increased risk for having another child with an NTD, and for an individual with spina bifida it is a 40 times greater than normal risk (Scarff and Fronczak, 1981; Stein et al., 1982).

Other, well-documented risk factors include young and advanced maternal age (Vieira and Castillo Taucher, 2005); maternal obesity (Stothard et al., 2009); maternal diabetes (Soler et al., 1976); maternal fever or flu (Lynberg et al., 1994); maternal caffeine consumption (Schmidt et al., 2009); specific maternal occupational exposures (Blanco Muñoz et al., 2005); maternal low educational level and socioeconomic status (Blanco Muñoz et al., 2005); maternal passive smoking (Wang et al., 2013); maternal periconceptual stressful event (Li et al., 2013); low maternal weight gain (Shaw et al., 2001); maternal use of folic acid antagonists such as valproic acid and/or carbamazepine (Hernández-Díaz et al., 2001; Lammer et al., 1987); preceding history of maternal miscarriage (Blanco Muñoz et al., 2006) or other birth defects (Yin et al., 2010); and higher birth order (Vieira, 2004).

Pathogenesis

Almost all infants born with spina bifida have an Arnold-Chiari malformation, which includes hindbrain herniation, brainstem abnormalities, low-lying venous sinuses, and a small posterior fossa (Adzick et al., 2011). This malformation is also associated with hydrocephalus and developmental brain abnormalities (Adzick et al., 2011). This affects motor, cranial nerve, and cognitive functioning. Hydrocephalus has traditionally been managed by diverting cerebral spinal fluid to the peritoneal cavity with a surgically placed shunt (Adzick et al., 2011). Endoscopic third ventriculostomy combined with choroid plexus cauterization effectively manages hydrocephalus in more than 70% of patients with myelomeningocele, avoids the need for placement of a ventriculoperitoneal (VP) shunt, and has similar neurocognitive outcomes as the VP shunt (Warf and

Campbell, 2008; Warf et al., 2009).

The neurologic lesion produced by the myelomeningocele can be variable, depending on what neural elements, if any, have everted with the meningocele sac. The bony vertebral level often provides little or no clue to the exact neurologic level or lesion produced. The height of the bony level may differ from the highest extent of the neurologic lesion for one to three vertebrae in either direction (Bauer et al., 1977). **Therefore, the neurologic lesion produced by this condition influences LUT function in a variety of ways and cannot be predicted just by looking at the spinal abnormality or the neurologic function of the lower extremities.** (Table 34.7 notes the distribution of spinal levels affected in myelomeningocele.)

Perinatal Concerns

Antenatal ultrasonography suggests the insult to central and peripheral nervous systems of a fetus with spina bifida is progressive, such that lower limb movement may be lost and hindbrain herniation and hydrocephalus may worsen during gestation (Korenromp et al., 1986; Sival et al., 1997). Animal studies have demonstrated that prenatal coverage of spina bifida–like lesions can preserve neurologic function and limit hindbrain herniation (Meuli et al., 1995). It is postulated that the ultimate neurologic deficit in spina bifida is the result of "two-hits": (1) the initial failure of neural tube formation and (2) ongoing injury to the exposed neural tissue in the intrauterine environment that results from mechanical and chemical trauma (Adzick et al., 2011; Meuli et al., 1995). Thus, it is suggested that in-utero intervention may improve outcomes for children with spina bifida.

To further evaluate this theory, a **randomized trial of prenatal surgery** before 26 weeks' gestation or standard postnatal repair of myelomeningocele, Management of Myelomeningocele Study (MOMS), was completed. The primary outcome (a composite of fetal or neonatal death or the need for a cerebrospinal fluid shunt) was reduced in the prenatal surgery group (relative risk 0.70). However, 40% of the prenatal closure group still required shunting, and not all experienced improved neuromotor function or complete resolution of hindbrain herniation. The second primary outcome (a composite score of mental development and motor function at 30 months) was also better in the prenatally treated group. No maternal deaths were reported. Fetal and neonatal deaths did not differ between the two groups. However, pregnancy complications, including oligohydramnios, chorioamniotic separation, placental abruption, need for transfusion at the time of delivery, and spontaneous membrane rupture, were more common in the prenatally treated group. One-third of women with prenatal surgery had an area of dehiscence or a very thin uterine surgical scar at the time of delivery. The fetuses that underwent prenatal surgery were much more likely to be preterm, with an average gestational age of 34.1 weeks (with 13% delivered before 30 weeks) compared with 37.3 weeks' gestation in the postnatal surgery group (with none delivered before 30 weeks). In addition, infants in the prenatal surgery group underwent more procedures for delayed spinal cord tethering and had a much higher rate of respiratory distress syndrome and a lower birth weight (Adzick et al., 2011).

Bladder Function After Prenatal Closure of Spina Bifida

Several early studies of a small number of children who underwent closure of the NTD in utero found that urodynamic parameters were similar to those published in the literature for children undergoing standard postnatal closure (Holmes et al., 2001; Holzbeierlein et al., 2000). A case-control series found that those with prenatal closure had a higher incidence of complete denervation of the external urinary sphincter and detrusor overactivity compared with those with postnatal closure (Koh et al., 2006). A recent small study of 8 patients reported lower rates of CIC and febrile urinary tract infections (UTIs) in children whose defects were closed prenatally (Horst et al., 2017). Larger studies with a comparative postnatal closure group confirmed that there is no difference in the need for CIC, bladder capacity, detrusor overactivity (Clayton et al., 2011; Lee et al., 2012b), incontinence between catheterizations, antimuscarinic use, antibiotic use, detrusor sphincter dyssynergia (Lee et al., 2012b), incidence of detrusor leak point pressure greater than 40 cm H_2O, vesicoureteral reflux (VUR), need for a comprehensive bowel regimen, or need for surgery including augmentation cystoplasty, continent catheterizable urinary channel procedure, or Malone antegrade continence procedure (Clayton et al., 2011). Minimally invasive fetoscopic repair of myelomeningocele also has been reported to be associated with similar urinary tract functional outcomes as patients are being repaired postnatally (Huang et al., 2017).

In summary, prenatal closure of spina bifida appears to improve neuromotor function and decrease the need for ventriculo-peritoneal shunting. However, this advantage comes with an increased risk for maternal morbidity and preterm labor with its resultant complications. In addition, there is clear evidence that bowel and bladder function are not improved and in some cases may be hindered with prenatal closure of spina bifida when compared with postnatal closure.

Initial Postnatal Management

Ideally, it would be best to perform urodynamic testing immediately after the infant is born, but the risk for spinal infection and the need for prompt spinal closure have not made this a viable option. However, it was accomplished in one study, and the results showed that 1 in 30 children (3.2%) experienced a change in neurologic status as a result of the spinal canal closure (Kroovand et al., 1990). Therefore, **renal ultrasonography and measurement of residual urine are performed as early as possible after birth,** typically after the spinal defect is closed and the patient has sufficiently recovered from surgery. Residual urine may be measured by ultrasonography or catheterization after the patient voids or leaks urine with the Valsalva maneuver (Bauer et al., 2012). Urodynamic studies (UDS) are delayed until it is safe to transport the child to the urodynamic suite and place him or her on the back or side for the test. However, it may not be practical to obtain UDS before initial discharge, and recent guidelines suggest UDS can be safely performed at 3 months without detriment to the infant (Routh et al., 2016). If the infant cannot empty the bladder after a spontaneous void, CIC is begun even before UDS are conducted. The normal bladder capacity in the newborn period is 10 to 15 mL; therefore, a residual urine volume of less than 5 mL is acceptable. A careful neurologic examination of the lower extremities should be undertaken as well. A serum creatinine and blood pressure are obtained at 3 months. Urine cultures are obtained as clinically indicated (Routh et al., 2016).

Once the spinal closure has healed sufficiently, renal ultrasonography is performed to assess upper urinary tract architecture and function. If voiding cystourethrography (VCUG) is not performed as part of a video urodynamic study, a separate VCUG should be obtained at 3 months. Evaluation for VUR is particularly important if hydronephrosis, ureteral dilation, renal size or contour discrepancy, or increased bladder wall thickness are observed on ultrasonography and/or detrusor overactivity, poor compliance, elevated leak point pressure, or detrusor-sphincter dyssynergia (DSD) (Bauer et al., 2012) are noted on UDS. A screening dimercaptosuccinic acid (DMSA) renal scan is recommended at 3 months (Routh et al., 2016). **These studies meet several objectives: they provide baseline information about the radiologic appearance of the upper and lower urinary tracts as well as the condition of the sacral spinal cord and the central nervous system (CNS); they provide information that can be compared with findings on subsequent assessments, so that early signs of deterioration of urinary tract function and drainage, or of progressive neurologic denervation, can be detected; they help identify infants at risk for urinary tract deterioration as a result of a poorly compliant or overactive detrusor or outflow obstruction from DSD, which predetermines the need to initiate prophylactic measures before any deterioration in upper urinary tract architecture and function actually takes place; and they help the physician to counsel parents about the child's future bladder and sexual function** (Bauer et al., 1984; Lais et al., 1993; McGuire et al., 1981; Bauer, 1984; Sidi et al., 1986)**.** The DMSA scan provides a different baseline, primarily the potential to determine progressive changes in upper urinary tract changes in relations to LUT dysfunction. Strategies to address inadequate bladder emptying are found in Table 34.2.

TABLE 34.2

Strategies to Address Inadequate Bladder Emptying in Children With Neurogenic Bladder Dysfunction

CAUSE OF INADEQUATE EMPTYING	MINIMALLY INVASIVE TREATMENT OPTIONS	MORE INVASIVE TREATMENT OPTIONS
Inadequate bladder contractions	CIC Overnight catheter drainage	Neuromodulation
Detrusor sphincter dyssynergia	CIC Antimuscarinic therapy Overnight catheter drainage	Intravesical and/or sphincteric botulinum toxin Augmentation cystoplasty Urinary diversion Neuromodulation

CIC, Clean intermittent catheterization.

Key Points: Evaluation of the Newborn With

Neurogenic Bladder Dysfunction

- Renal ultrasonography and measurement of residual urine are performed as early as possible after birth.
- Initial evaluation can be compared with findings on subsequent assessments so that early signs of deterioration of urinary tract function and drainage, or of progressive neurologic denervation, can be detected.
- Infants at risk for urinary tract deterioration as a result of a poorly compliant or overactive detrusor or outflow obstruction from DSD need to be identified. This determines the need to initiate prophylactic measures before any deterioration in upper urinary tract architecture and function take place.
- Three categories of LUT dynamics may be detected: synergic (26%), dyssynergic with and without poor detrusor compliance (37%), and complete denervation (36%).

Findings

When first evaluated on radiologic examination, 5% to 10% of newborns have an abnormal urinary tract (Bauer, 1985), 3% have hydroureteronephrosis secondary to spinal shock, probably from spinal canal closure (Chiaramonte et al., 1986), and 15% have abnormalities that developed in utero as a result of abnormal LUT function in the form of outlet obstruction (Bauer, 2003).

UDS in the newborn period have shown that 63% of infants have bladder contractions. This is also true for an equivalent number of children with upper lumbar or thoracic lesions in whom the sacral spinal cord is spared, 50% of whom have detrusor overactivity (Pontari et al., 1995). Thirty-seven percent have an acontractile detrusor with compliance during filling that is either good (20%) or poor (17%) in this subgroup (Bauer, 2003; Bauer et al., 1984). Electromyographic (EMG) assessment of the external urethral sphincter demonstrates an intact sacral reflex arc with no evidence of lower motor neuron denervation in 40% of newborns; partial denervation is seen in 24%, and complete loss of sacral cord function is noted in 36% (Bauer, 2003; Lais et al., 1993).

Prediction of Risk for Upper Urinary Tract Deterioration

A combination of bladder contractility and external sphincter activity results in **three categories of LUT dynamics: synergic (26%), dyssynergic with and without poor detrusor compliance (37%), and complete denervation (36%)** (Figs. 34.2 and 34.3) (Bauer, 2003; Sidi et al., 1986). DSD occurs when the external sphincter fails to decrease or actually increases its activity during a detrusor contraction or a sustained increase in intravesical pressure as the bladder is filled to capacity (Blaivas et al., 1981). Frequently, a poorly compliant bladder with high intravesical pressure occurs in conjunction with a dyssynergic sphincter, resulting in a bladder that empties only at high intravesical pressure (Sidi et al., 1986) (Fig. 34.4). Synergy is characterized by complete silencing of the sphincter during a detrusor contraction or when capacity is reached at the end of filling. Voiding pressures are usually within the normal range. Complete denervation is noted when no bioelectric potentials are detectable in the region of the external sphincter at any time during the micturition cycle or in response to sacral stimulation or the Credé maneuver.

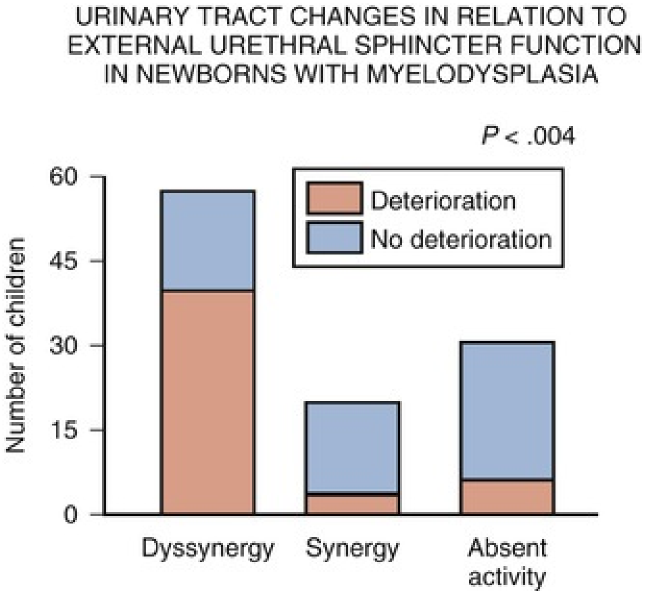

FIG. 34.2 Urinary tract deterioration is related to outflow obstruction and is most often associated with dyssynergy. Children with synergy converted to dyssynergy, and patients with complete denervation developed fibrosis with a fixed high outlet resistance in the external sphincter before any changes occurred in the urinary tract. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, ed. *Urologic surgery in neonates and young infants.* Philadelphia, PA: WB Saunders; 1988:252–264.)

FIG. 34.4 (A) A voiding cystourethrogram in a female neonate with dyssynergy and elevated voiding pressures demonstrates no reflux and a smooth-walled bladder. The initial renal echogram was normal. The patient was started on clean intermittent catheterization and oxybutynin chloride (Ditropan) but did not respond. Within 1 year, she developed right hydronephrosis (B, *arrows*) and severe reflux, evident on a radionuclide cystogram (C).

Categorizing LUT function in this way has been extremely useful because it reveals which children are at risk for urinary tract changes, who should be treated prophylactically, and who need close surveillance. Within the first 3 years of life, 71% of newborns with DSD had urinary tract deterioration on initial assessment or subsequent studies, whereas only 17% of synergic children and 23% of completely denervated individuals developed similar changes (see Fig. 34.2). Infants in the synergic group who showed deterioration did so only after they converted to a dyssynergic pattern of sphincter function. Among the infants with complete denervation, the ones who showed deterioration were those who had increased levels of urethral resistance, presumably caused by fibrosis of the skeletal muscle component of the external sphincter. Therefore, it appears that bladder outlet obstruction is a major contributor to the development of urinary tract deterioration in these children. Poor detrusor compliance plays an important role in this regard, especially when bladder outlet resistance exceeds 40 cm H_2O (Landau et al., 1994; McGuire et al., 1981; Tanaka et al., 1999) and the patient is not on a CIC program that empties the bladder regularly. Detrusor compliance seems to be poorer in children with high levels of outlet resistance (Ghoniem et al., 1989).

It may be that detrusor filling pressures need to be looked at in a more critical way to determine whether they are an important factor in upper urinary tract deterioration. **Landau et al.** (1994) **developed the concept of low detrusor filling pressure (< 30 cm H_2O) at specific volumes adjusted for age and not at maximal capacity.** Applying this notion, they reported significantly improved sensitivity in predicting upper urinary tract deterioration. Recently, a Centers for Disease Control and Prevention (CDC)-sponsored spina bifida management protocol categorized UDS into four groups: hostile bladder, intermediate risk, abnormal but safe, and normal. Hostile bladder was defined as end filling pressure or detrusor leak point pressure (DLPP) 40 cm H_2O or greater or neurogenic detrusor overactivity (NDO) with detrusor sphincter dyssynergia.

Intermediate risk was defined as NDO, reduced compliance, and end filling pressure or DLPP 25 to 39 cm H_2O. Abnormal but safe was defined as end filling pressure or DLPP less than 25 cm H_2O. Normal bladder was defined as normal capacity, compliance greater than 15 cm H_2O, no NDO, no detrusor sphincter dyssynergia, and minimal postvoid residual.

Early Intervention in Children With Spina Bifida

The concept of early intervention for children with detrusor sphincter dyssynergia, poor detrusor compliance, high bladder outlet pressures, and outflow obstruction was introduced in the early 1990s (Bauer et al., 1984; McGuire et al., 1981; Sidi et al., 1986). Early intervention is herein defined as CIC and antimuscarinic therapy. There has been some controversy about the benefit of early intervention in children with spina bifida; however, **there is a plethora of data that document its beneficial effects on long-term outcomes in this population.**

Effect of Early Intervention on Bladder Function

In one study of 26 newborns with DSD and high bladder pressures treated with CIC and oxybutynin, this drug eliminated overactive contractions in 2 of 14 children and lowered peak contractile pressure in the remaining 12 children (Fig. 34.5). It was also noted to lower bladder filling pressure at capacity in all 12 patients with poor compliance (Kasabian et al., 1992). Minimal side effects were noted from its use and none from CIC (Kasabian et al., 1992). Early intervention also results in improved continence (Kaefer et al., 1999). One study found that up to 44% of children treated with early intervention were dry at 6 years of age (Dik et al., 2006).

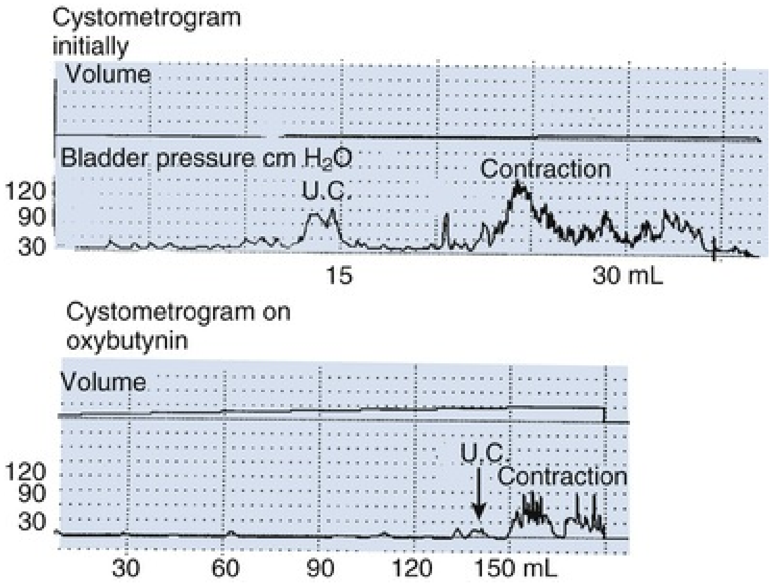

FIG. 34.5 Oxybutynin is a potent anticholinergic agent that dramatically delays detrusor contractions and lowers contraction pressure, as demonstrated on these two graphs. *U.C.,* Uninhibited contraction.

Early Initiation of Clean Intermittent Catheterization Decreases the Rate of Urinary Tract Infection

Studies of expectant management document UTI in 50% of children by 15 months of life and 81% by 15 years of age. In addition, recurrent UTIs are common, with more than 44% of children having 5 episodes of UTI and almost 10% having more than 20 episodes (Filler et al., 2011). However, in children following early institution of CIC, the mean number of infections is 0.3 per year (Wide et al., 2012). Several studies have demonstrated a decreased rate of UTI when CIC is utilized, either within the same patient (Olandoski et al., 2011) or in contrast with a comparative group (Kari et al., 2009).

Early Intervention Decreases Upper Urinary Tract Deterioration

The potential for development of hydroureteronephrosis in children with high-risk bladders including DSD is well established. In one study, 72% with dyssynergia later developed hydronephrosis (Bauer et al., 1984). Other studies note the risk for development of hydroureteronephrosis varied from 18% to 80% in children with high-risk bladders who were treated expectantly (Edelstein et al., 1995; Geraniotis et al., 1988; Kaefer et al., 1999; Kochakarn et al., 2004).

Development of hydrouteronephrosis is much less common in trials of early intervention, ranging from 0% to 15% (Dik et al., 2006; Edelstein et al., 1995; Geraniotis et al., 1988; Kaefer et al., 1999). The importance of preventing upper urinary tract deterioration is underscored by one study that reported renal impairment in 6.6% and DMSA abnormalities in 30% of newborns with spina bifida at their initial evaluation (Sager et al., 2017).

Early Intervention Reduces the Rate of Vesicoureteral Reflux

Studies of expectant management of children with myelodyspasia and high-risk bladders identify VUR in up to 50% of patients by 9 years of age (Filler et al., 2011). In children managed with CIC from birth, the development of VUR is much less common (28%) (Wide et al., 2012). Another study also found that children treated with CIC early had a much lower incidence of VUR than those who were not on therapy or were noncompliant with therapy (62% vs. 92%) (Kari et al., 2009).

Early Intervention Decreases the Need for Surgery

Several studies comparing early intervention to expectant therapy have noted a lower need for surgery in children with high-risk bladders. Up to 11% of children treated expectantly may require urinary diversion (Filler et al., 2011). Comparatively, no child required renal protective surgery in a group of 41 children treated with early intervention. In fact, only 1 child in this group required surgery for incontinence, and 6 had injection of botulinum A toxin (BTA) (Wide et al., 2012). Others have documented an 18% to 24% reduction in the need for bladder augmentation when early intervention is compared with expectant management (Kaefer et al., 1999; Kochakarn et al., 2004).

Early Intervention Decreases the Incidence of Renal Scarring and End-Stage Renal Disease

Early intervention does not appear to be advantageous for those children who can empty their bladder spontaneously (Torre et al., 2011). Studies of historical cohorts document evidence of renal scarring in 27% to 50% of children (Filler et al., 2011; Lewis et al., 1994; Müller et al., 2002). The rate of renal scarring in children treated with early intervention is much lower, ranging from 4% to 12% (Dik et al., 2006; Torre et al., 2011; Wide et al., 2012). As anticipated, the decrease in renal scarring relates to a decreased incidence of end-stage renal disease (ESRD) in children treated with early intervention (0% to 1.6%) (Dik et al., 2006; Malakounides et al., 2013; Torre et al., 2011) compared with those managed expectantly (30%) (Rickwood et al., 1984).

Assessment of Renal Function in Children With Neuromuscular Dysfunction of the Lower Urinary Tract

Although serum creatinine is a widely used marker of glomerular filtration rate (GFR), it is known to be a poor marker of renal function in children with neurogenic bladder dysfunction. Its serum level is dependent on age, gender, height, and, most importantly, muscle mass (Pham-Huy et al., 2003). Individuals with reduced muscle mass may demonstrate a low endogenous creatinine release that may not result in an elevated creatinine level despite a decrease in GFR (Quan, 1997). Numerous studies have confirmed that serum creatinine is not an accurate reflection of GFR in children with spina bifida, who often have diminished muscle mass (Filler and Lepage, 2003; Pham-Huy et al., 2003; Quan, 1997). **The gold standard for measuring GFR is the renal scan, which is invasive and exposes the patient to radiation.** Thus it is preferable to have a serum marker that will closely reflect GFR in this specific population with a high risk for renal functional impairment.

Small–molecular-weight proteins, such as cystatin C, have been suggested as alternative markers of GFR for children with neuromuscular dysfunction of the urinary tract (Pham-Huy et al., 2003). As cystatin C is determined primarily by glomerular filtration, these levels correlate more closely with GFR than that obtained when estimated by the Schwarz formula or other small–molecular-weight proteins (Abrahamsson et al., 2008; Pham-Huy et al., 2003). However, cystatin C is not widely available, and it is limited by inflammation and changes in protein catabolism (Filler and Lee, 2018).

Kidney Size in Children With Spina Bifida

Sutherland et al. noted that children with spina bifida had smaller kidneys than their normal peers and generated a nomogram for renal size in this population (Sutherland et al., 1997). Others have confirmed this finding of small renal size in some children with spina bifida (del Gado et al., 2003; Montaldo et al., 2014).

It was initially suggested that a potential cause could be low levels of growth hormone, but this has been excluded by the demonstration of normal levels of insulin-like growth factor-1 (del Gado et al., 2003; Montaldo et al., 2014). A study of newborns with spina bifida found those with small kidneys and their mothers had high serum levels of homocysteine. Specifically, children and mothers with homocysteine levels greater than 10 µmol/L were more than twice as likely to have small kidneys and to give birth to children with small kidneys (Montaldo et al., 2014). These infants also had a higher incidence of intrauterine growth restriction. As hyperhomocysteinemia has been linked to placental vasculopathy, it has been postulated that the mechanism for small renal size in children with spina bifida might be related to abnormal placental function (Montaldo et al., 2014). Small renal size in children with spina bifida has been associated with decreased renal function (del Gado et al., 2003).

Renal Dysfunction in Spina Bifida

Several studies have identified that surrogate markers of renal dysfunction in children with spina bifida are frequently abnormal. For example, 54% and 19% of children referred to nephrologists for recurrent UTI were noted to have microalbuminuria and metabolic acidosis, respectively (Olandoski et al., 2011). The rate of hypertension in myelodyspastic children ranges from 12% to 41% (Rickwood et al., 1984; Mazur et al., 2011; Olandoski et al., 2011). This is significantly higher than national age-matched control groups (3%) (Mazur et al., 2011). The risk for hypertension is positively correlated with maximum body mass index (Mazur et al., 2011). Hypertension is more frequently noted after puberty and in those with renal scarring (Rickwood et al., 1984).

Some degree of renal dysfunction has been detected in 30% to 50% of children with spina bifida (Malakounides et al., 2013; Müller et al., 2002). Historical studies determined an incidence of end-stage renal disease (ESRD) in 18% of children before and 30% of children after puberty (Rickwood et al., 1984). Others have found that ESRD is an outcome in 15% of those with spina bifida (Lee, 2010). More contemporary studies in which early intervention with CIC and antimuscarinics were used noted much lower rates of renal dysfunction (6%) and ESRD (0% to 1.6%) (Dik et al., 2006; Malakounides et al., 2013; Torre et al., 2011).

Determinants of Risk for Renal Dysfunction in Spina Bifida.

There has been much investigation regarding the determinants of renal functional loss in children with spina bifida. In most studies, renal deterioration or dysfunction is defined as altered renal function as measured by creatinine, creatinine clearance, or renal scarring noted on DMSA renal scans. Urodynamic findings associated with increased incidence of renal deterioration, such as hydronephrosis, VUR, and renal scarring include detrusor sphincter dyssynergia (Bauer et al., 1984; Ozel et al., 2007); high detrusor pressures (Arora et al., 2007; Ozel et al., 2007; Wide et al., 2012); and detrusor overactivity (Ozel et al., 2007). The association between history of febrile UTI and renal scarring in this population is well documented (Ozel et al., 2007; Shiroyanagi et al., 2009). The presence of hydronephrosis (Arora et al., 2007; DeLair et al., 2007; Ozel et al., 2007; Torre et al., 2011) and VUR (Arora et al., 2007; DeLair et al., 2007; Ozel et al., 2007; Torre et al., 2011) is also associated with renal scarring. However, one study using multivariate analysis demonstrated that a high-pressure bladder and hydronephrosis in the absence of VUR was not associated with renal cortical loss (DeLair et al., 2007). Lack of compliance with recommended therapy has also been shown to be an important factor in the development of renal scarring in this population (Kari et al., 2009; Wide et al., 2012).

Key Points: Early Intervention and Renal Function in Neural Tube Defects

- Early intervention with CIC and antimuscarinics improves urodynamic parameters; decreases the rate of UTI, VUR, and upper urinary tract deterioration; and decreases the incidence of ESRD.
- Cystatin C is superior to serum creatinine in monitoring renal function in children with neural tube defects. Renography is the gold standard for estimating GFR.
- Determinants of risk for renal dysfunction in spina bifida include detrusor sphincter dyssynergia, high detrusor pressures, detrusor overactivity, febrile UTI, and VUR. These entities should be actively managed to minimize the risk for renal functional decline.

Sexual Function

Sexuality in this population is becoming an increasingly important issue as more individuals reach adulthood and want to have intimate relationships

(Cromer et al., 1990). Many psychosocial factors play a role in the development and sexual maturation of children with spina bifida. Parents and health care workers are often reluctant to discuss sexual development with adolescents (Joyner et al., 1998; Sandler et al., 1996; Woodhouse, 1998). In addition, teens with spina bifida often experience social isolation (Dorner, 1977; Joyner et al., 1998). This is supported by studies showing that children with spina bifida are less likely than those without spina bifida to have peers acting as their main source of sexual education (Decter et al., 1997; Dorner, 1977). Some children with spina bifida are dependent on others for their activities of daily living and therefore often live with parents or an alternative caregiver (Börjeson and Lagergren, 1990). Young men with spina bifida reported better erectile function and intercourse satisfaction when they lived independently (Gamé et al., 2006). **Parents of children with spina bifida tend to be more overprotective than parents of normal children and are less willing to grant autonomy to them for adequate peer and sexual development** (Holmbeck et al., 2002). When asked about sexual function, many teens with spina bifida report that their parents are often very overprotective (Dorner, 1977). Parental permissiveness in social participation and age-appropriate treatment by parents contribute positively to high self-esteem in these adolescents (Wolman et al., 1994). In a study of life satisfaction of Dutch young adults with spina bifida, the highest proportion of dissatisfaction was found for partnership relations (49%) and sex life (55%). **More than 50% of young adults with spina bifida report that they are dissatisfied with their current sex life** (Barf et al., 2007; Verhoef et al., 2005a).

Boys reach puberty at an age similar to the age for boys without spina bifida, whereas breast development and menarche tend to start as much as 2 years earlier than usual in girls with spina bifida compared with girls without spina bifida. The average age at menarche in girls with spina bifida varies between 10.9 and 11.4 years of age (Trollmann, 1998). The cause of this early hormonal transformation is uncertain, but it may be related to changes in pituitary function in girls secondary to hydrocephalus (Hayden et al., 1979).

Sexual education specific to individuals with spina bifida should be provided. Latex-free condoms are mandatory for those with latex allergy or those adhering to latex avoidance recommendations. The use of estrogen/progestin contraceptives may increase the risk for thromboembolic events in those with decreased mobility, and using intrauterine devices for contraception is unsafe because of the risk for pelvic infections (Jackson and

Mott, 2007).

The degree of sexuality is inversely proportional to the level of neurologic dysfunction (Gatti et al., 2009; Joyner et al., 1998; Palmer et al., 1999). In addition, lower occurrence of sexual activity seemed to be noted in populations with greater rates of incontinence and more severe disability (Barf et al., 2007; Börjeson and Lagergren, 1990; Cardenas et al., 2008; Gatti et al., 2009; Sandler et al., 1996; Verhoef et al., 2005a). Those with the lowest lesion levels are most likely to form partnerships (Gatti et al., 2009). Increasing age is associated with increased likelihood of having a partner; those older than 26 years of age were 2.1 times more likely to have a partner than those 18 to 25 years of age (Gatti et al., 2009). The absence of hydrocephalus is a positive predictor of sexual activity (Barf et al., 2007; Verhoef et al., 2005a). This effect is more pronounced for women than for men (Cardenas et al., 2008). Females are more likely than males to be sexually active (Barf et al., 2007; Cardenas et al., 2008; Sawyer and Roberts, 1999; Verhoef et al., 2005a), **but females with spina bifida are at risk for sexual abuse.** Unwanted sexual attention was reported by 37% and unwanted sexual touching was noted by 30% of women with spina bifida, whereas 4% of men with spina bifida have experienced improper sexual touching (Sawyer and Roberts, 1999).

In several studies, researchers interviewed groups of teenagers with spina bifida and reported that **28% to 40% of them had had one or more sexual encounters, and almost all of them had a desire to marry and ultimately to bear children** (Cromer et al., 1990; Palmer et al., 1999). Seventy percent of those with spina bifida desire sexual contact (Barf et al., 2007; Verhoef et al., 2005a). Common features of studies evaluating sexual function in adolescents and young people with spina bifida include low participation rates because of patient/parental refusal and elimination of patients with severe physical disabilities and/or severely compromised intellectual function. This results in a very select population in which only highly functioning individuals are investigated. Five of six studies found that **more than 70% of young men with spina bifida were able to obtain an erection** (range 70% to 92%) (Börjeson and Lagergren, 1990; Cass et al., 1986; Decter et al., 1997; Diamond et al., 1986; Sandler et al., 1996). A more recent study reported that only 40% of men with spina bifida had normal erections, with ambulatory status the likely collolary associated with erectile function, and 63% of ambulators more likely to report normal erections compared with 15.8% of nonambulators (Roth et al., 2017). In another series, **the ability to ejaculate ranged from approximately 40% to**

75% (Börjeson and Lagergren, 1990; Cass et al., 1986; Decter et al., 1997; Sandler et al., 1996). In some cases, retrograde ejaculation was noted (Sandler et al., 1996). Self-report of sexual activity varied greatly with different study populations, ranging from 8% to 83% for males (Börjeson and Lagergren, 1990; Cass et al., 1986; Decter et al., 1997; Laurence and Beresford, 1975; Sandler et al., 1996) and 23% to 69% for females (Börjeson and Lagergren, 1990; Cass et al., 1986).

Reports suggest that **70% to 80% of women with spina bifida were able to become pregnant and to have an uneventful pregnancy and delivery,** although urinary incontinence in the latter stages of gestation was common in many, as was delivery by cesarean section (1975 Arata et al., 2000; Bomalaski et al., 1995; Cass et al., 1986; Laurence and Beresford, 1975). In the same studies, 17% to 39% of male subjects claimed that they were able to father children, and another 25% had a favorable prognosis for fathering them (Bomalaski et al., 1995; Decter et al., 1997; Laurence and Beresford, 1975). **Both women and men with spina bifida have an increased risk for having a child with spina bifida** compared with individuals without spina bifida (3.7% incidence of spina bifida in offspring) (Bong, 2007). This effect is more pronounced in women (Chatkupt et al., 1992). If both parents have spina bifida, the risk for having a child with spina bifida increases to 15% (Cameron and Moran, 2009). To reduce this risk, women with spina bifida should be counseled about taking a 4- to 5-mg supplement of folic acid daily before even contemplating getting pregnant (Visconti et al., 2012). It is more likely that men will have problems with erectile and ejaculatory function because the sacral spinal cord is frequently involved, whereas reproductive function in women, which is under hormonal control, is not affected. Men with neurologic lesions at S1 or lower are likely to have normal or adequate reproductive sexual function, but only 50% of those with lesions above that level have adequate function (Woodhouse, 1994, 2005). Poor semen quality (Hultling et al., 2000) and Sertoli cell only histology on testis biopsy (Glass and Soni, 1999) have been reported as reasons (in addition to erectile dysfunction) for infertility in men with spina bifida.

One study used a validated questionnaire, the International Index of Erectile Function (IIEF) to evaluate sexual function in men older than 18 years of age with spina bifida (Gamé et al., 2006). Overall, 75% had erectile dysfunction. Of 16 men who recently had sexual intercourse, 4 had no erectile dysfunction, 3 had mild dysfunction, 4 had mild to moderate dysfunction, and 5 had severe dysfunction. Erectile function was directly related to the ability to maintain erections and the presence of a sacral nerve root lesion (Gamé et al., 2006). A more recent study of 47 men using the IIEF reported a 51.1% rate of sexual intercourse, but 87% reported more than mild sexual dysfunction; however, 67% and 50% had normal erectile and orgasmic function, respectively. Furthermore, sexual function and quality of life were associated statistically (Choi et al., 2017). The role of intact pelvic parasympathetic reflex activity has a positive correlate in men with spina bifida (Diamond et al., 1986; Sandler et al., 1996). The Female Sexual Function Index (FSFI) has been used to evaluate sexual function in women with spina bifida (Choi et al., 2018). In this study, sexual dysfunction was noted in 55.5% of women. In sexually active women, VP shunt, mobility status, and CIC did not show a significant difference among each subdomain (desire, arousal, lubrication, orgasm, satisfaction, and pain) and the total FSFI score. However, women who did not have urinary incontinence experienced better sexual function in terms of lubrication and pain scores. Both the physical and mental composites of quality of life were positively correlated with the arousal score of FSFI. Another recent study using the IIEF and FSFI to determine sexual function in 45 patients with spina bifida reported sexual dysfunction in 89% of women and 59% of men (Lee et al., 2015). Individuals with spina bifida of either gender tended to have more severe dysfunction compared with those who had sexual dysfunction of other etiologies, except with similar sexual desire scores. Thus, patients of both genders with spina bifida experienced high rates of sexual dysfunction.

Medical therapy for erectile dysfunction has been shown to be effective in this population. Sildenafil improved erectile function in 80% of men with myelomeningocele in a randomized, double-blind, placebo-controlled trial (Palmer et al., 1999). Some promise has been achieved with attempts to restore penile sensation in men with spina bifida by connecting the sensory ilioinguinal nerve microsurgically to the ipsilateral dorsal nerve of the penis in men with normal groin sensation (Jacobs et al., 2013; Overgoor et al., 2013) Preliminary results in small case series showed increased sensation of the ipsilateral glans penis, better overall sexual function, and increased satisfaction (Overgoor et al., 2013), but these findings await long-term studies.

Management of Neurogenic Bowel Dysfunction in Spina Bifida

Options for the management of constipation traditionally include dietary modification, digital stimulation, laxatives, enemas, and biofeedback therapy.

Management in children with neurogenic bowel must to be tailored to the individual's ability to address mobility/balance, ability for self-care, manual dexterity, and anal sphincter tone.

Two-thirds of children 6 years of age and older and one-third of children 16 to 25 years of age with spina bifida report fecal incontinence, which has a substantial impact on their quality of life (Krough et al., 2003; Verhoef et al., 2005b). Most recommend a **graduated approach** to the management of constipation in this population (Burgers et al., 2013; Choi et al., 2013a, 2013b; Velde et al., 2007). **Initially, treatment is directed toward high dietary fiber and osmotic laxatives** (Choi et al., 2013b; Velde et al., 2007). Polyethylene glycol has been shown to be more effective in this population than lactulose (Rendeli et al., 2006). An option for those who are unable to sit on the toilet is **controlled constipation with manual evacuation of stool** as large-volume enemas cannot easily be delivered in these children (Velde et al., 2007). In those who are able sit independently, with some anal sphincter activity, a regular postprandial toilet-sitting regime 3 times a daily after meals has been effective, as it employs the gastrocolic reflex to initiate a bowel movement (Velde et al., 2007). When continence is not achieved by defecation, **digital stimulation** is suggested (Velde et al., 2007). If manual evacuation fails or if the anal sphincter is nonfunctioning, **retrograde enemas** (tap water with irrigation cone followed by kneading of the abdomen or alternative transanal irrigation devices (Ausili et al., 2010) are instituted (Shandling and Gilmour, 1987; Velde et al., 2007). Initially, enemas are given daily, and, if successful, the frequency can be decreased to every second day. Initial enema volume is 500 mL and increased to 1L, if required. If fecal incontinence persists at this point, the **antegrade continence enema (ACE)** is considered the next step in management. An ACE can be instituted on a daily basis initially, but can be reduced to 4 to 5 times a week depending on its effectiveness. Volumes used range between 1 to 2 liters (Velde et al., 2007). This stepwise approach to fecal pseudocontinence was successful in 69% of patients with spina bifida, and 10% achieved full fecal continence. Of those who were pseudocontinent, 16% used manual evacuation, 10% used a toileting scheme, 42% used a retrograde enema, and 32% used an ACE (Velde et al., 2007). The addition of polyethylene glycol (GoLYTELY), mineral oil, polyethylene glycol 3350 (MiraLAX), or glycerin to tap water enemas has successfully increased the continence rate for ACE regimens (Bani-Hani et al., 2008).

Malone was first to describe an ACE delivered through a surgically placed appendicostomy or cecostomy in children with spina bifida or anorectal malformation (Malone et al., 1990). It has been shown to significantly improve fecal continence, not increase the amount of time dedicated to bowel care, and improve quality of life (Ok and Kurzrock, 2011). Anal plugs may be effective for some patients during specific activities, such as swimming (Velde et al., 2007). Long-term studies indicate that approximately 40% of children discontinue using their surgically created cecostomies after a median of 11 years. Reasons for non-use include lack of effectiveness, complications, psychological issues, and poor compliance (Yardley et al., 2009). In those who continue using the cecostomy, their level of satisfaction is very high (Yardley et al., 2009). Shandling described placement of a percutaneous cecostomy under fluoroscopic guidance for delivery of the ACE in children with spina bifida (Shandling et al., 1996). This provides the advantage of avoiding laparotomy or laparoscopy.

Initial Diagnostic Evaluation and Follow-Up of Congenital Neurogenic Dysfunction in Children

The initial diagnostic evaluation of neurogenic bladder dysfunction will be discussed as it relates to specific pathologic processes throughout this chapter. The International Children's Continence Society (ICCS) has published general recommendations for follow-up of congenital neurogenic bladder, which are a compilation of best practices resulting from a paucity of high-level evidence (Bauer et al., 2012). The recommendations are based on developmental stages and associated growth spurts in the first 2 years of life and during early adolescence that may increase the risk for spinal cord tethering, and are summarized in Table 34.3. An example of the magnetic resonance imaging (MRI) findings in a case of spinal tethering is shown in Fig. 34.6. A recent study has noted that in adulthood, patients followed at a multidisciplinary spina bifida clinic presented with a urologic issue at a median of 12 months, and 40% had an asymptomatic urologic issue at 36 months. This suggests that a follow-up period of 12 to 18 months in adulthood may be prudent (Duplisea et. al., 2014).

TABLE 34.3

Summary of the International Children's Continence Society Recommendations for the Diagnostic Evaluation and Follow-Up of Congenital Neurogenic Bladder

RECOMMENDED

AGE GROUP	TYPE OF INVESTIGATION	FREQUENCY OF INVESTIGATION	INDICATION FOR INVESTIGATION
Newborn to toddler	Ultrasonography	Every 6 months until 2 years of age	High risk for tethering with rapid growth
	UDS	Every 12 months	UTIs or lower extremity changes
	DMSA renal scan	When indicated	Consider if VUR on initial VCUG/RNC or febrile UTIs
Toddler to adolescent	Ultrasonography	Every 12 to 24 months	Low risk for tethering with slower growth
	UDS	When indicated	Change in ambulation or lower extremity function
	DMSA renal scan	When indicated	Febrile UTIs
Adolescent to adult	Ultrasonography	Every 12 months	Low risk for tethering with slower growth; may decrease to every 24 months once growth velocity has decreased
	UDS	When indicated	Development of hydronephrosis, more frequent CIC required for continence, new wetting, recurrent UTI
	VCUG/RNC	When indicated	Recurrent UTI
Adult	Ultrasonography	Every 36 months	Low risk for tethering without ongoing somatic growth
	UDS	When indicated	Development of hydronephrosis, more frequent CIC required for continence, new wetting, recurrent UTI

CIC, Clean intermittent catheterization; *DMSA,* dimercaptosuccinic acid; *RNC* radionuclide cystography; *UTI,* urinary tract infection; *UDS,* urodynamic studies; *VCUG,* voiding cystourethrography; *VUR,* vesicoureteral reflux.

Management of Neuromuscular Dysfunction of the Lower Urinary Tract

The primary principle in management of neuromuscular dysfunction of the LUT is preservation of renal function. Secondary goals include attaining urinary continence, avoiding UTI, and facilitating sexual function and fertility. **Preservation of renal function is best achieved by maintaining low bladder pressures, avoiding hydronephrosis, and actively managing VUR, especially if recurrent UTIs are present.** The ICCS has published general recommendations for the evaluation and follow-up of patients with congenital neurogenic bladder, which are a compilation of expert opinions resulting from a paucity of high-level evidence (Bauer et al., 2012). These recommendations are based on developmental stages and associated growth spurts in the first 2 years of life and during early adolescence that may increase the risk for spinal cord tethering and are summarized in Table 34.3. More recently, a multicenter group endorsed by the Centers for Disease Control and Prevention (CDC) published a protocol for the urologic management of children birth to 5 years of age (Table 34.4). As of this writing, 22 sites in the United States are participating in the CDC National Spina Bifida Patient Registry (NSBPR).

CIC, Clean intermittent catheterization; *DMSA,* dimercaptosuccinic acid; *GFR,* glomerular filtration rate; *RBUS,* renal and bladder ultrasonography.

From Bauer, 2012.

Initial efforts to reduce bladder pressures include minimally invasive therapy to reduce bladder pressures such as CIC and antimuscarinic therapy. If this is unsuccessful, overnight indwelling catheter drainage has been shown to improve or resolve hydronephrosis, increase bladder capacity, and decrease the frequency of UTI (Koff et al., 2005; Nguyen et al., 2005). Those who have failed conservative management require surgical intervention. When choosing a surgical intervention, consideration must be given to the patient's ambulatory status, body habitus, manual dexterity, compliance with therapy, and capacity to provide self-care.

The normal bladder functions by storing urine at low pressures and empties by coordinating decreased outlet resistance with a bladder contraction. In neuropathic dysfunction, incontinence may result from failure of proper storage, emptying, or both. Storage may be compromised by low compliance, low capacity, overactive bladder contractions, and low bladder outlet resistance. Emptying may be compromised by inadequate bladder contractions or detrusor sphincter dyssynergia. Tables 34.2 and 34.5 indicate some possible options to address the failure of storage and emptying, respectively, in neuropathic dysfunction of the LUT in children, and the specific medical and surgical treatment options are described.

TABLE 34.5

Strategies to Address Inadequate Bladder Storage in Children With Neurogenic Bladder Dysfunction

CAUSE OF INADEQUATE STORAGE	MINIMALLY INVASIVE TREATMENT OPTIONS	MORE INVASIVE TREATMENT OPTIONS
Low compliance	CIC Antimuscarinic therapy Overnight catheter drainage	Intravesical botulinum toxin Augmentation cystoplasty Urinary diversion
Low capacity	Antimuscarinic therapy Overnight catheter drainage	Intravesical botulinum toxin Augmentation cystoplasty Urinary diversion
Overactive bladder contractions	CIC Antimuscarinic therapy Overnight catheter drainage	Intravesical botulinum toxin Augmentation cystoplasty Urinary diversion
Low bladder outlet resistance	Sympathomimetic therapy	Bladder neck sling Bladder neck procedure Injection of bulking agents into bladder neck

CIC, Clean intermittent catheterization.

Key Points: Management of Neuropathic Dysfunction of the Lower Urinary Tract

- The primary goal of management is preservation of renal function.
- Secondary goals of management include urinary/fecal continence, avoidance of UTI, and facilitation of sexual function and fertility.
- Preservation of renal function is achieved by maintaining low bladder filling pressures, active management of VUR, and avoiding UTI.
- The ICCS recommendations for follow-up are based on developmental stages and the relative risk for secondary spinal cord tethering.
- The CDC-endorsed multicenter collaborative has published a protocol for the management of patients with neurogenic bladder from birth to 5 years of age.
- Minimally invasive approaches should precede the use of more invasive therapies to address bladder failure to store urine efficiently or empty

effectively.

Medical Management of Neuropathic Dysfunction of the Lower Urinary Tract

See Table 34.6 for a summary of medications. Antimuscarinic drugs are the first-line treatment for detrusor overactivity (Hood and Andersson, 2013). The detrusor smooth muscle has M_2 and M_3 receptors, but M_2 predominate in number; however, $M_{3,}$ receptors mediate the direct contractile effects of acetylcholine in the detrusor (Hegde and Eglen, 1999). Initial response rates are favorable, but adverse effects and decreasing efficacy result in dwindling long-term compliance (Hood and Andersson, 2013). Use of antimuscarinics in children with detrusor overactivity results in increased bladder capacity, increased bladder volume to first detrusor contraction, and decreased number of incontinence episodes and number of catheterizations (Alloussi et al., 2010; Bolduc et al., 2010; Christoph et al., 2007; Ellsworth et al., 2005; Nijman et al., 2005; Reddy et al., 2008). Common adverse events include dry mouth, constipation, blurred vision, facial flushing, dizziness, and headache (Alloussi et al., 2010; Bolduc et al., 2010; Christoph et al., 2007; Ellsworth et al., 2005; Nijman et al., 2005; Reddy et al., 2008). There have been concerns about potential adverse cognitive effects of antimuscarinics, but a prospective, randomized, double-blind trial showed no negative effect of antimuscarinic medications on attention or memory (Giramonti et al., 2008).

TABLE 34.6

Medications for Management of Neuropathic Lower Urinary Tract Dysfunction

TYPE	MINIMUM DOSAGE	MAXIMUM DOSAGE
ANTICHOLINERGIC		
Oxybutynin (Ditropan)	0.2 mg/kg bid	0.2 mg/kg qid
Glycopyrrolate (Robinul)	0.01 mg/kg bid	0.03 mg/kg tid
Hyoscyamine (Levsin)	0.03 mg/kg bid	0.1 mg/kg qid
Tolterodine (Detrol)	0.01 mg/kg bid	0.04 mg/kg bid
Trospium (Sanctura)	0.1 mg/kg bid	0.3 mg/kg bid
Fesoterodine (Toviaz)	0.06 mg/kg qd	0.12 mg/kg qd
SYMPATHOMIMETIC		

Pseudoephedrine (alpha) (Sudafed)	0.4 mg/kg bid	0.9 mg/kg tid
Mirabegron (beta 3) (Myrbetriq)	0.3 mg/kg qd	0.3 mg/kg bid
Sympatholytic		
Doxazosin (alpha) (Cardura)	0.01 mg/kg qd	0.02 mg/kg qd
Tamsulosin (Flomax)	0.01 mg/kg qd	0.02 mg/kg qd
Terazosin (Hytrin)	0.015 mg/kg qd	0.06 mg/kg qd
Other		
Imipramine (Tofranil)	0.7 mg/kg bid	1.2 mg/kg tid

bid, Twice a day; *tid,* three times a day; *qd,* once a day; *qid,* four times a day.

The most commonly used antimuscarinic agent in children is oxybutynin, a tertiary amine with primary affinity for M_3 receptors. It may be delivered orally, transcutaneously (Cartwright et al., 2009), or intravesically (Guerra et al., 2008). Oral dosing is usually done at 0.2 mg/kg/dose given up to three times daily. Oral preparations include tablets, syrup, and extended-release tablets. All three have been shown to be safe and effective in children (Franco et al., 2005). The transdermal doses is 3.9 mg daily (Cartwright et al., 2009). The transdermal route has been shown to be well-tolerated and an effective alternative to oral oxybutynin in children with neurogenic detrusor overactivity. Skin irritation is noted in some patients, which leads to discontinuation of treatment in 20% of children (Cartwright et al., 2009; Gleason et al., 2014). A systematic review noted a low level of evidence for the intravesical use of oxybutynin that is thought to result in fewer adverse effects by avoiding first-pass metabolism. It did increase maximum bladder capacity and decrease bladder fill pressure with lower side effects than oral administration; however, 9% of children discontinued using it as a result of adverse effects and 22% because of other issues such as inconvenience of administration (crushing pills to prepare the solution) (Guerra et al., 2008).

Tolterodine, a tertiary amine (antimuscarinic), has been noted to inhibit nonvoiding bladder activity and the amplitude of voiding contractions (Gillespie et al., 2012). In children with neurogenic detrusor overactivity, tolterodine was shown to be well tolerated, with minimal treatment-related adverse events because of its inability to cross the blood-brain barrier, and to increase functional bladder capacity in children younger than 10 years of age while decreasing the mean number of incontinence episodes with long-term (12 month) use (Reddy et al., 2008).

Fesoterodine is a tertiary amine antimuscarinic with affinity to M_3 receptors. Its active metabolite, 5-hydroxy-methyltolteride, is the same as tolterodine, but fesoterodine has less pharmacokinetic variability and fewer adverse events than tolterodine (Malhotra et al., 2011). It has been shown to be safe and tolerable in children with daily doses of 4 mg and 8 mg (Malhotra et al., 2012). Its main benefit is that a methyl group has been added, which allows the drug to bypass the cytochrome oxidase enzymes that convert tolterodine to its active form, thus providing a more effective antimuscarinic drug (Chapple et al., 2007).

Trospium, a quaternary amine antimuscarinic, crosses the blood brain-barrier but has minimal affinity for intracerebral M_1 receptors, so its rate of adverse events is markedly diminished. It has a considerably prolonged mechanism of action compared with oxybutynin ($T_{1/2}$ of 8 vs. 2 hours). Its improvement in LUT urodynamic parameters and clinical symptoms are significant, with only 8% reporting any adverse event (Lopez Pereira et al., 2003).

Solifenacin is a once-daily tertiary amine antimuscarinic, also with affinity for M_3 receptors, that has been shown to increase urodynamic bladder capacity, decrease overactive contractions, and improve continence with acceptable tolerability and safety in an open-label study of children with neurogenic and non-neurogenic detrusor overactivity who were recalcitrant to oxybutynin or tolterodine therapy (Bolduc et al., 2010). In this study, 21% had mild effects, 4% had moderate effects, and 5% withdrew because of intolerable adverse effects.

Propiverine is a calcium channel blocker. Preventing intracellular influx of calcium inhibits Rho kinase action on actomyosin fibrils and limits the enzymatic action on actomyocin ATPase by binding to calmodulin. In several studies, LUT symptoms (Allousi et al., 2009) and especially urodynamic parameters were improved to a greater extent than with oxybutynin, with a statistically significant change for patients receiving propiverine versus either their own pretreatment UDS or compared with those given oxybutynin, respectively (Madersbacher et al., 2009; Schulte-Baukloh et al., 2006). In another prospective analysis, 17 children had increased bladder capacity and reduced detrusor pressure greater than 60%, with incontinence improving in 53% of those who were incontinent before treatment (Schulte-Baukloh et al., 2012).

Mirabegron is a novel β_3-adrenegic receptor agonist that decreases the number of micturitions and continence (Yamaguchi et al., 2014). It works by stimulating β_3 receptors located throughout the fundus of the bladder that, when stimulated, elicit relaxation of the detrusor muscle by activating adenylyl cyclase, causing increases in the intracellular levels of cyclic AMP and calcium (Chapple et al., 2014). It is effective in adults but has not yet been approved by the U.S. Food and Drug Administration (FDA) for use in children. Two recent studies using mirabegron alone or in combination with solifenacin in children with idiopathic overactive bladder reported acceptable tolerability and efficacy (Blais et al., 2016; Morin et al., 2017).

Sympathomimetic Agents (Fig. 34.7)

If incontinence results from inadequate urethral resistance, sympathomimetic agents such as ephedrine HCl (0.5 to 1 mg/kg/day three times a day and pseudoephedrine (0.4 mg/kg twice a day to 0.9 mg/kg three times a day) act to increase tone at the bladder neck, where the concentration of alpha-adrenergic receptors is highest, thereby raising outlet resistance and improving continence. It is hard to predict which children might respond to these drugs that potentially increase bladder outlet resistance by stimulating receptors in the trigone and bladder neck, but in some cases there is a dramatic increase leading to continence between CIC (Bauer, 2014). Regular use of sympathomimetic agents, however, may be limited by their adverse effects, which include dizziness, nausea, nervousness, insomnia, loss of appetite, headache, mood changes, and urinary retention.

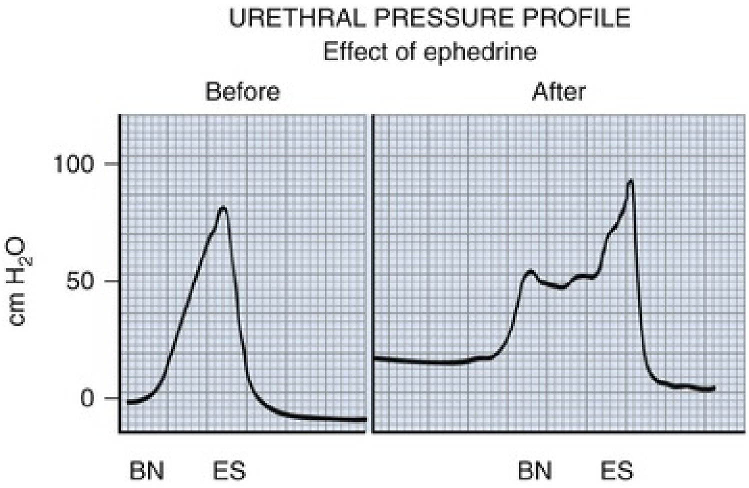

FIG. 34.7 α-Sympathomimetic agents potentially have their greatest effect in the bladder neck region, where the highest concentration of α-adrenergic receptor sites exists. They can raise outlet resistance and improve continence in many individuals. *BN,* Bladder neck; *ES,* external sphincter.

Surgical Treatment Options for Neuropathic Dysfunction of the Lower Urinary Tract

Botulinum Toxin

An alternative option for detrusor overactivity in neurogenic bladder is the intravesical injection of BTA. BTA is a neurotoxin protein produced by the gram-positive bactrium, *Clostridium botulinum;* it acts by inhibiting acetylcholine release resulting in muscle paralysis. BTA has also been found to inhibit the release of other neurotransmitters including adenosine triphosphate and neuropeptides such as substance P, and to downregulate the expression of purinergic and capsaicin receptors on afferent neurons within the bladder (Apostolidis et al., 2006; Chapple and Patel, 2006). Specifically, it substantially reduces muscle cell expression for M_2, M_3, P2x2 and P2x3 receptors that lead to detrusor muscular paralysis (Schulte-Baukloh et al., 2013). The first use of BTA to treat neurogenic detrusor was in adults with spinal cord injury (SCI) (Dykstra and Sidi, 1990). The first use in children with neuropathic bladder was documented in 2002 (Schulte-Baukloh et al., 2002). The most commonly injected dose varies from 5 to 9.6 *IU*/kg with a maximum dose of 360 *IU*. Most studies use 30 injection sites, sparing the trigone with rigid cystoscopy under general anesthesia. Sixty-five percent to 87% of children who have failed conservative medical management and CIC achieved dryness with a BTA injection (Riccabona et al., 2004). Improvements in urodynamic parameters include decreased maximum detrusor pressure (33% to 57%); increased maximum cystometric capacity (34% to 165%); and improved compliance (121% to 183%). The duration of response ranges from 6 to 10.5 months (Gamé et al., 2009; Hascoet et al., 2018). The most common minimal age for injection was 2 years, which corresponds to that approved by the FDA for the treatment of cerebral palsy (CP) (Gamé et al., 2009).

Overall patient and caregiver satisfaction with this treatment is greater than 70% (Figueroa et al., 2014). Injection of BTA may allow approximately 25% of patients to discontinue antimuscarinic therapy after the first injection and an additional 10% after a second injection (Figueroa et al., 2014). Side effects from BTA are infrequently reported by patients (Kask et al., 2014). Side effects of intravesical BTA injection include urinary retention, UTI, hematuria, transient muscle weakness, dysuria, and pain (Duthie et al., 2011; Hascoet et al., 2018). It appears that repeated injections continue to be effective, with the interval between repeated injections increasing with each series of injections (Altaweel et al., 2006; Schulte-Baukloh et al., 2005). A reduction of dose in repeat injections (from 300 *IU* to 200 *IU*) was associated with recurrence of symptoms, which resolved with reinstitution of the original dosing regimen (Figueroa et al., 2014). Injection of intradetrusor BTA avoided bladder augmentation in close to 90% of children who had failed first-line treatment with CIC and antimuscarinics (Figueroa et al., 2014). Serial injections of BTA show additional, significant improvement in urodynamic parameters, suggesting that tachyphylaxis, neutralizing antibody formation, or progressive fibrosis are not considerations with repeat BTA injections (Figueroa et al., 2014). This finding is supported by histopathologic examination of the detrusor. One study found no significant difference in edema, inflammation, or fibrosis when comparing children with neurogenic dysfunction before their first injection with those having had a previous intradetrusor injection of BTA. Repeated injections were associated with a significant decrease in the amount of fibrosis compared with those who had no history of injection (Pascali et al., 2011).

Children who respond poorly to BTA intradetrusor injection may have preexisting poor bladder compliance (Kask et al., 2014). Complete lack of response to BTA injection has been linked to the presence of BTA antibodies (Schulte-Baukloh et al., 2008, 2011), but another study found no differences in antibody formation and response to BTA despite the number of injections (Kajbafzadeh et al., 2010). One study compared injection of BTA in the detrusor to injection in both the detrusor and external urinary sphincter in 60 children with neurogenic dysfunction who had failed CIC and antimuscarinic therapy. More than 90% of this cohort had DSD documented before injection of BTA. They found those with BTA injected into the external urethral sphincter had a significant improvement in postvoid residual urine measurement and the presence of DSD on follow-up UDS. Additionally, clinical parameters including constipation and incontinence trended toward improvement in the group with injections into the external urethral sphincter, although this improvement was not statistically significant (Safari et al., 2010). A larger study is required to confirm these preliminary findings.

For a thorough discussion of more invasive surgical options for neurogenic bladder in children including augmentation, autoaugmentation, urinary diversion, bladder neck procedures, and the artificial urinary sphincter (AUS), please refer to ExpertConsult.com.

Surgical Management of Neuropathic Dysfunction of the Lower Urinary Tract

Augmentation

A persistent poorly compliant, small-capacity, and/or overactive bladder may be treated with enterocystoplasty (Mitchell and Piser, 1987; Sidi et al., 1987). It is estimated that in the early 2000s, approximately 5.4% of children with spina bifida underwent augmentation cystoplasty (Lendvay et al., 2006). Sigmoid, cecum, stomach, and small intestine have been used to enlarge the bladder. The ileocecal segment is avoided in children with spina bifida because removing it might aggravate the bowel dysfunction in these children (Bauer, 2014). Detubularization of the bowel is needed to minimize the intrinsic contractions of the intestinal segment and prevent it from causing intractable incontinence once it has been added to the bladder (Goldwasser et al., 1987; Hinman, 1988).

Most studies evaluating outcomes for augmentation cystoplasty have patient populations that compromise mixed etiologies (primarily neurogenic bladder caused by spina bifida, but also other causes; exstrophy-epispadias; and posterior urethral valves) and are performed with and without concomitant procedures such as continent catheterizable channels, antireflux surgery, and bladder outlet surgery, thus there is limited data that reflect the outcomes specifically in those with neurogenic bladder treated with augmentation cystoplasty in isolation. Continence is achieved in 90% or more (Husmann and Cain, 2001; Quek and Ginsberg, 2003; Shekarriz et al., 2000; Veenboer et al., 2013). Mean bladder capacity (Krishna et al., 1995; Quek and Ginsberg, 2003), improved compliance (Veenboer et al., 2013), and safe storage pressures (Krishna et al., 1995; Quek and Ginsberg, 2003) are achieved in most patients. Preexisting hydronephrosis resolves in up to 92% (Krishna et al., 1995).

Postoperative UDS may reveal regular phasic contractions (Robertson et al., 1991). It is unclear if these contractions arise from the bowel segment or the remaining bladder. These contractions are generally of low-amplitude activity (<40 cmH_2O) and are volume dependent, occurring only at volumes greater than 200 mL (Quek and Ginsberg, 2003). Zero percent to 29% of patients require antimuscarinics after augmentation (Chartier-Kastler et al., 2000; Herschorn and Hewitt, 1998; Luangkhot et al., 1991; Mitchell et al., 1986; Quek and Ginsberg, 2003).

Complications of Augmentation Cystoplasty.

The complication rate of augmentation cystoplasty is approximately 30% (Metcalfe et al., 2006b; Schlomer et al., 2013). Approximately one-half of those are considered to be major (Schlomer et al., 2013), and they include small bowel obstruction (Schlomer et al., 2013), bleeding requiring transfusion (in cases using gastric segments) (Schlomer et al., 2013), fistula (Schlomer et al., 2013), bladder perforation (Metcalfe et al., 2006b), and recurrent UTIs/pyelonephritis (Bertschy et al., 2000; DeFoor et al., 2004; Flood et al., 1995). The need for further surgery is estimated to be 0.04 operations per patient per year. Additional surgery may include intervention for stones (11% to 63%) (DeFoor et al., 2004; Flood et al., 1995; Metcalfe et al., 2006a), laparotomy for bowel obstruction (3.2% to 4%) (Flood et al., 1995; Metcalfe et al., 2006a), closure of bladder perforation (4% to 13%) (Bauer et al., 1992; Bertschy et al., 2000; DeFoor et al., 2003; Flood et al., 1995; Krishna et al., 1995; Metcalfe et al., 2006b; Shekarriz et al., 2000), and revision of or repeat augmentation (9.4% to 16%) (Flood et al., 1995; Metcalfe et al., 2006a).

Risk factors for development of stones in augmented bladders include excessive mucus production from enteric segments (Hensle et al., 2004), use of the ileal segment (DeFoor et al., 2004; Metcalfe et al., 2006b), presence of an abdominal stoma (Hensle et al., 2004), and an immobile patient with sensory impairment (Hensle et al., 2004). Stone formation recurs in up to 30% (DeFoor et al., 2004; Flood et al., 1995). Periodic irrigation with water or saline is recommended to decrease the rate of stone formation related to mucus (Hensle et al., 2004).

Bladder perforation is a life-threatening complication of bladder augmentation that requires prompt diagnosis and treatment. In some individuals, it is a recurring problem (Metcalfe et al., 2006b). Presenting symptoms include abdominal distension and pain, septic shock, and shoulder pain related to diaphragmatic irritation from extravasated urine (Bauer et al., 1992). Sepsis has resulted in death of 25% presenting with bladder perforation (Bauer et al., 1992). Those with a history of bladder outlet surgery seem to be at increased risk (Bauer et al., 1992; Metcalfe et al., 2006b). It appears that individuals with a catheterizable abdominal stoma are at lower risk for perforation (Metcalfe et al., 2006b), perhaps as a result of increased compliance with catheterization schedules (Horowitz et al., 1995). Controversy exists regarding which bowel segment has the highest risk for rupture. Some studies have identified the sigmoid colon as the most likely to perforate, although most of the sigmoid segments in this series were not detubularized (Metcalfe et al., 2006b), and others have identified the ileum as most likely to rupture (Bauer et al., 1992). With this risk for sepsis and death, diagnosis and treatment must be immediate. Cystography (either fluoroscopic or computed tomography [CT]) is diagnostic in most but not all cases (Bauer et al., 1992; Slaton and Kropp, 1994). Overdistension and relative ischemia related to bowel detubularization are important factors in the pathophysiology of rupture (Bauer et al., 1992). The gold standard approach to management is exploratory laparotomy and closure of the perforation; however, conservative management with drainage of the urinary reservoir and percutaneous drainage of abdominal urinoma, in those without hemodynamic instability or worsening symptoms has been described, especially if the leak is extraperitoneal (Leyland and Masters, 2003; Slaton and Kropp, 1994).

Long-term metabolic complications are also common with augmentation cystoplasty. **Concerns have surfaced about gastric segments because they can cause hyponatremic hypochloremic metabolic alkalosis** (Gosalbez et al., 1993) or the hematuria dysuria syndrome (Castellan et al., 2012). Except for children with progressive or end-stage renal failure, gastrocystoplasty is not recommended currently as a routine form of augmentation (Chadwick Plaire et al., 2000; Leonard et al., 2000). Augmentation cystoplasty with any segment of the gastrointestinal tract can lead to long-term consequences in acid-base balance, vitamin B_{12} deficiency, fat absorption, renal function changes, aberrant bone metabolism, and growth retardation (Gilbert and Hensle, 2005).

There seems to be an increased risk for bladder cancer in patients with spina bifida who have been augmented (Austin et al., 2007). Proposed risk factors for the development of malignancy in spina bifida include chronic UTI, stone disease, repeat catheterization, and incorporating enteric segments (Mehan et al., 2011). Early reports suggested that intestinal and gastric bladder augmentation were associated with an increased risk for bladder cancer. The largest study found that bladder cancer developed in 0.6% of patients undergoing augmentation (Metcalfe et al., 2006a). Most studies note a 10-year minimum lag time between the augmentation and presentation of disease. Presenting symptoms are often atypical and may include vague abdominal pain, gross hematuria, urosepsis, renal failure, difficult catheterization, increasing frequency of UTI, new-onset hydronephrosis, and bladder wall thickening (Austin et al., 2007; Castellan et al., 2007; Veenboer and de Kort, 2011; Vemulakonda et al., 2008). Patients also present at a younger age than is typical for these cancers (Austin et al., 2007; Veenboer and de Kort, 2011). One study found that almost

90% of patients presented with locally advanced disease or lymph node metastases (Austin et al., 2007). Urothelial cell carcinoma accounts for close to 60% of the tumors, followed by squamous cell carcinoma in 21%, adenocarcinoma in 16%, and signet cell tumor of the gastric augment in 5% (Austin et al., 2007). Some studies have disputed the association of enteric augmentation with increased risk for malignancy as there have also been reports of malignancy in those with autoaugmentation without incorporation of enteric segments (Mehan et al., 2011; Veenboer and de Kort, 2011). In addition, several studies have found that enteric augmentation in this group does not result in a greater risk for developing malignancy than in a comparable group of patients without augmentation (Austin et al., 2007; Higuchi et al., 2010). Most of these studies are compromised because of relatively small study numbers and confounding factors, such as a history of smoking, exposure to known carcinogens, and family history, all of which are not addressed. A recent systematic review reported on the outcomes in 52 patients with spina bifida from 28 studies that included patients with and without bladder augments (Rove et al., 2017). In this review, it was reported that the overall risk for bladder cancer in patients with spina bifida in 2% to 4%. Overall survival at 1 and 2 years was 48.5% and 31.5%, respectively, and there was no difference in overall survival based on age, management with an indwelling catheter, diversion with an ileal conduit, or being on a surveillance program. However, overall survival was poorer for those with augmentation. Thus, it is clear that patients with neurogenic bladder affected by bladder malignancy present at a young age, with atypical symptoms and with advanced disease. Some, including the ICCS, have recommended annual surveillance cystoscopy and cytology starting 5 to 10 years after augmentation (Castellan et al., 2007; Rawashdeh et al., 2012; Soergel et al., 2004; Vemulakonda et al., 2008). However, there is insufficient evidence to determine the efficacy of screening for bladder cancer in this population (Kokorowski et al., 2011). In fact, 4 of 6 cases diagnosed with bladder cancer had no discernible mass noted during routine cystoscopic surveillance (Castellan et al., 2007; Vemulakonda et al., 2008). In addition, hypothetical models predict that screening for bladder cancer after augmentation cystoplasty is not cost-effective (Kokorowski et al., 2011).

Alternatives to standard augmentation cystoplasty have been sought to avoid the short- and long-term complications associated with this procedure. Although initial reports of autologous tissue–engineered bladder augmentation using cell-seeded polyglycolic acid–collagen scaffolds was promising (Atala et.al., 2006), a recent phase II study showed that bladder capacity and compliance were not improved and the incidence of serious adverse events was unacceptable (Joseph et al., 2014). Similar unsatisfactory results were noted with bladder augmentation using small intestine submucosa (SIS) (Schaeffer et al., 2013).

Autoaugmentation

As augmentation with enteric segments has a significant risk for short- and long-term complications, some have advocated autoaugmentation or detrusorectomy (with or without demucosalized enteric segments) to treat small and poorly compliant neurogenic bladders (Cartwright and Snow, 1989a; 1989b). Although some have shown short-term improvement in bladder capacity, compliance, and maximum detrusor pressures (Hansen et al., 2013), when compared with enteric augmentation, those who have had autoaugmentation are more apt to be incontinent, use antimuscarinics, and have poorer compliance (MacNeily et al., 2003; Marte et al., 2002; Veenboer et al., 2013). The incidence of de novo hydronephrosis (30%) (MacNeily et al., 2003) and VUR (Marte et al., 2002) in autoaugmentation is unacceptably high. The failure rate of autoaugmentation and need for subsequent augmentation cystoplasty ranges from 15% to 45% (Hansen et al., 2013; MacNeily et al., 2003; Marte et al., 2002; Veenboer et al., 2013). The lack of long-term improvement in urodynamic parameters and continence, combined with the high failure rate, make autoaugmentation an undesirable option.

Urinary Diversion

Urinary diversion, once considered a panacea for children with spina bifida, has turned out to be a Pandora's box of new clinical problems (Schwarz and Jeffs, 1975; Shapiro et al., 1975). Pyelonephritis and renal scarring, urinary tract calculi, ureterointestinal obstruction, strictures of the conduit, and stomal stenosis are often encountered in children who are monitored on a long-term basis. In recent times, urinary diversion is rarely performed, unless accompanied by a continent catheterizable stoma.

Incontinent Urinary Diversion.

Button vesicostomy was first described in 1996 using a gastrostomy button (de Badiola et al., 1996). It has the advantage of being readily reversible and can be used as a temporary solution. The incidence of minor complications such as transient leakage, wound infection, and overgranulation are expected in 40% of patients, with 17% requiring removal or replacement of the device for infection, device failure, and significant leakage (Bradshaw et al., 2014).

Vesicostomy drainage (Duckett, 1974; Mandell et al., 1981) is rarely required today but is reserved for those infants (1) who have such severe reflux that CIC and antimuscarinic medication fail to improve upper urinary tract drainage, (2) whose parents cannot adapt to the catheterization program, or (3) who are not good candidates for augmentation cystoplasty (Morrisroe et al., 2005). It has been shown to improve renal function, hydronephrosis, and VUR in almost all patients undergoing the procedure (Queipo Zaragozá et al., 2003). Complications include bladder stomal prolapse, stomal stenosis, peristomal irritation, and vesical lithiasis (Queipo Zaragozá et al., 2003).

Ileovesicostomy is suggested to be advantageous over vesicostomy because an external appliance can be applied to the stoma that eliminates the need for diapers (Ching et al., 2014). Although short-term results look promising (Ching et al., 2014), long-term follow-up reveals over one-half of children require reoperation or additional procedures (Hellenthal et al., 2009; Tan et al., 2008).

Urethral Dilation.

External urethral dilation (up to 36 F in infants or up to number 18 Hegar dilators in older children) under general anesthesia has been described to address elevated leak point pressures in select children with neurogenic bladder dysfunction who have not responded to CIC and antimuscarinic therapy (Bloom et al., 1990). The mean number of dilations needed per patient is 1.6 (Park et al., 2001). The dilation in males can be achieved via perineal urethrostomy (Bloom et al., 1990; Miller et al., 2003). Durable (mean follow-up of 8 years) improvement has been demonstrated in mean leak point pressure, capacity, and initial and terminal compliance (Bloom et al., 1990; Park et al., 2001). Those with an elevated leak point pressure and good initial compliance seem to have the most long-lasting results from the procedure. However, upper urinary tract deterioration was noted in 20%, by about 9.5 years after the dilation (Park et al., 2001). Approximately 43% have improvement in VUR, and 64% have an improvement or resolution of hydronephrosis (Kiddoo et al., 2006). Thus, urethral dilation may benefit a select group of children with neurogenic bladder who fail initial conservative measures, but long-term follow-up is compulsory.

Bladder Neck Procedures

Artificial Urinary Sphincter.

In children with low bladder outlet resistance, the AUS provides increased outlet resistance while maintaining the ability to catheterize per urethra. In children, the sphincter may be placed at the bladder neck or bulbar urethra (in males). It is often performed in conjunction but not simultaneously with other procedures such as augmentation cystoplasty to address poor compliance and low bladder volumes. Continence rates range from 63% to 86% (Catti et al., 2008; Herndon, 2003; Simeoni et al., 1996; Spiess et al., 2002). The need for revision ranges from 16% to 61% (Catti et al., 2008; Herndon, 2003; Simeoni et al., 1996; Spiess et al., 2002), with erosion of the cuff noted in 16% to 20% (Castera, 2001; Catti et al., 2008; Herndon, 2003; Simeoni et al., 1996). Worsening bladder function is noted in 4% to 30% (Catti et al., 2008; Castera, 2001; Simeoni et al., 1996). This is seen more commonly in those with a preexisting poorly compliant or with overactive bladder. Long-term surveillance is required in all patients as they may develop bladder hypertonicity after outlet resistance is increased, which can lead to upper urinary tract changes and eventual renal failure (Castera, 2001). Patients with an AUS are less likely to void spontaneously if the sphincter is implanted before puberty or in conjunction with augmentation cystoplasty (Catti et al., 2008). Mean operational life of the AUS ranges from 4.6 to 12.7 years (Castera, 2001; Simeoni et al., 1996; Spiess et al., 2002). Better continence outcomes are noted in those without a history of a prior bladder neck procedure (Castera, 2001).

Bladder Neck Slings.

It is difficult to compare published data concerning the effectiveness of bladder neck slings in the treatment of bladder outlet incompetence, as most published series include patients with varied preoperative bladder function and previous or concurrent procedures, such as augmentation cystoplasty, bladder neck reconstruction, and continent catheterizable channels. As well, there is no standardized definition of continence. In addition, varied materials are utilized to perform the sling including rectus fascia (Bauer et al., 1989; Walker et al., 1995), bladder wall (Albouy et al., 2007), and small intestinal submucosa (Colvert, 2002; Misseri et al., 2005a). Success rates for continence appear to be similar despite varied sling materials, although rectus fascia is used most commonly. Both *U*-shaped and 360-degree type slings are described (Bauer et al., 1989; Snodgrass et al., 2007). Irrespective of technique, similar continence rates are noted. In those with decreased bladder compliance or overactivity, bladder neck slings are usually performed in conjunction with augmentation cystoplasty, yielding continence rates of 30% to 93%, with most studies noting success in excess of 70% (Albouy et al., 2007; Barthold et al., 1999; Churchill et al., 2010; Dik et al., 2006; Walker, 1995). Continence rates for females tend to be better than for males with a bladder neck sling (Barthold et al., 1999; Colvert, 2002). Most studies note that bladder neck slings do not lead to difficulty with catheterization (Albouy et al., 2007; Churchill et al., 2010; Dean and Kunkle, 2009). Some have advocated using a bladder neck sling alone, without augmentation in children with neurogenic sphincter deficiency, bladder underactivity, and a low detrusor leak point pressure less than 25 cm H_2O (Snodgrass et al., 2007). Continence, defined as two or fewer wet pads per day, is noted in 83% (Snodgrass et al., 2007). However, as noted in those with increased outlet resistance after placement of an AUS (Bauer et al., 1986), these patients are at risk for developing overactivity and decreased bladder compliance. Approximately one-third of patients treated with a tight 360-degree bladder neck sling developed increased bladder pressures and/or overactive detrusor contractions (Snodgrass and Barber, 2010; Snodgrass et al., 2007). Most of these children responded to antimuscarinic treatment, although augmentation cystoplasty was required in 2 of 37 patients (5%) (Snodgrass and Barber, 2010; Snodgrass et al., 2010). Therefore, if bladder neck sling is done in isolation, long-term surveillance is required to monitor for changes in bladder function to prevent upper urinary tract deterioration. When compared with those having a bladder neck sling without augmentation, patients with augmentation have a longer interval between catheterizations, require less antimuscarinic medication, and scored higher on a health-related quality of life survey for achieving independence for self-directed care (Snodgrass et al., 2009). For children who do not achieve continence with a bladder neck sling, placement of an AUS is likely to be more effective than injection of periurethral bulking agents (Barthold et al., 1999).

Injection of Periurethral Bulking Agents

Over time, the type of material injected to increase outlet resistance at the bladder neck has changed; currently, the most common agent used is dextranomer/hyaluronic acid (Alova et al., 2012; DaJusta et al., 2013). Success rates for achieving complete continence with retrograde, transurethral injection of the bladder neck are low, ranging from 7% to 50%, with deterioration in results over time (Alova et al., 2012; DaJusta et al., 2013; De Vocht et al., 2010;

Godbole et al., 2003; Guys et al., 2001, 2006; Lottmann et al., 2006; Misseri, Casale, et al., 2005b). Repeat injections do not appear to be beneficial (Alova et al., 2012; De Vocht et al., 2010). Success in those with antegrade injection of bulking agent and suprapubic catheter drainage postinjection is much better, ranging from 70% to 78% (Alova et al., 2012; Dean et al., 2007; Kaye et al., 2010). Thus, although the success rates are low, bladder neck injection of bulking agents does achieve dryness for some children with neurogenic sphincter deficiency. Antegrade injection has superior success rates than retrograde injection.

Electrostimulation

Most studies of electrostimulation in pediatric neurogenic bladder involve a small sample size, often lack a control group, and have varied methods of electrostimulation and different outcome measures. Although some studies have shown improvement in clinical and urodynamic parameters, larger, prospective, randomized trials are required (Balcom et al., 1997; Choi et al., 2013a; Cirović et al., 2009; Decter et al., 1992, 1994; Godec and Cass, 1978; Han et al., 2004; Kajbafzadeh et al., 2009; 2010; Marshall and Boston, 1997).

Sacral Neuromodulation

Sacral neuromodulation has been used extensively in children with non-neurogenic bladder dysfunction. Its use in children with neurogenic dysfunction has been limited. One prospective, randomized study of 42 children with spina bifida comparing standard conservative management and sacral neuromodulation found that urodynamic variables did not differ between the two groups, with the exception of better functional bladder capacity in the control group and lower leak point pressure in the neuromodulation group (Guys et al., 2004). Some of those in the implant group noted improved intestinal transit, resolution of UTI, and better sensation of a persistently full bladder (Guys et al., 2004). Seven percent of the neuromodulation group required revision surgery (Guys et al., 2004). Thus, sacral neuromodulation in this population appears to be safe with some limited benefits over standard therapy, but a larger study is required to determine its efficacy.

Artificial Somatic-Autonomic Reflex Pathway

Procedure

The artificial somatic-autonomic reflex pathway is a procedure involving a limited laminectomy and a lumbar ventral root to S3 ventral root microanastomosis. The L5 dorsal root is left intact as the afferent branch of the somatic-autonomic reflex pathway after axonal regeneration (Xiao et al., 2005). Despite reported improvements in urinary and bowel function in early small series (Peters et al., 2010; Xiao et al., 2005), a prospective, randomized, double-blind study showed no benefit (Tuite et al., 2016). In addition, significant postoperative complications that have been reported included prolonged wound drainage, ipsilateral foot drop, and temporary lower extremity muscle weakness (Peters et al., 2010). Thus this procedure has been largely abandoned.

Key Points: Medical and Surgical Treatment Options

- Antimuscarinic therapy and CIC are the mainstay of therapy.
- Bladder filling pressures should be maintained below 30 cm H_2O as much as possible to prevent upper urinary tract deterioration.
- Intravesical injection of BTA is well tolerated and avoids the need for more invasive treatment options in a high proportion of children with minimal side effects.
- Enterocystoplasty is an effective option to prevent upper urinary tract deterioration but comes with a high risk for complications.
- Patients undergoing isolated bladder neck procedures (AUS and bladder neck sling) may develop detrusor overactivity and poor compliance that leads to upper urinary tract deterioration, mandating close follow-up.

Management of Vesicoureteral Reflux in Neuropathic Dysfunction of the Lower Urinary Tract

VUR occurs in 3% to 5% of neonates with spina bifida, usually in association with poor detrusor compliance, detrusor overactivity, and/or DSD (Flood et al., 1994). It is rare to find reflux in any neonate without these urodynamic findings (Bauer, 1984; Edelstein et al., 1995; Geraniotis et al., 1988). If left untreated, the incidence of reflux in these infants at risk increases with time until 30% to 40% are afflicted by 5 years of age (Bauer, 1984a; Seki et al., 1999). In children with reflux grades 1 to 3 (International Classification) who void spontaneously or have a complete lesion with little or no bladder outlet resistance and empty their bladder completely, management consists solely of prophylaxis with antibiotics to prevent recurrent infection. In children with high-grade reflux (grade 4 or 5), CIC is begun to ensure complete emptying. Children who cannot empty their bladder spontaneously, regardless of the grade of reflux, are treated with CIC to improve emptying efficiency.

Children with poor detrusor compliance with or without hydroureteronephrosis are also started on antimuscarinic agents to lower intravesical pressure and ensure adequate upper urinary tract decompression (Flood et al., 1994). When reflux is managed thusly, there has been a dramatic response, with resolution in 30% to 55% of individuals (Agarwal et al., 1997 Bauer, 1984; Flood et al., 1994; Hopps and Kropp, 2003; Joseph et al., 1989; Kass and Koff, 1981). Although bacteriuria can be seen in as many as 56% of children on CIC, it is not harmful except in the presence of high-grade reflux, because symptomatic urinary infection and renal scarring rarely occur with lesser grades of reflux (Cohen et al., 1990; Kass and Koff, 1981).

Credé voiding should be avoided in children with reflux, especially those with a reactive external urethral sphincter. In this circumstance, the Credé maneuver results in a reflex response in the external sphincter that increases urethral resistance and raises the pressure needed to expel urine from the bladder (Barbalias et al., 1983) (Fig. 34.8). This has the effect of aggravating the degree of reflux and accentuating its waterhammer effect on the kidneys.

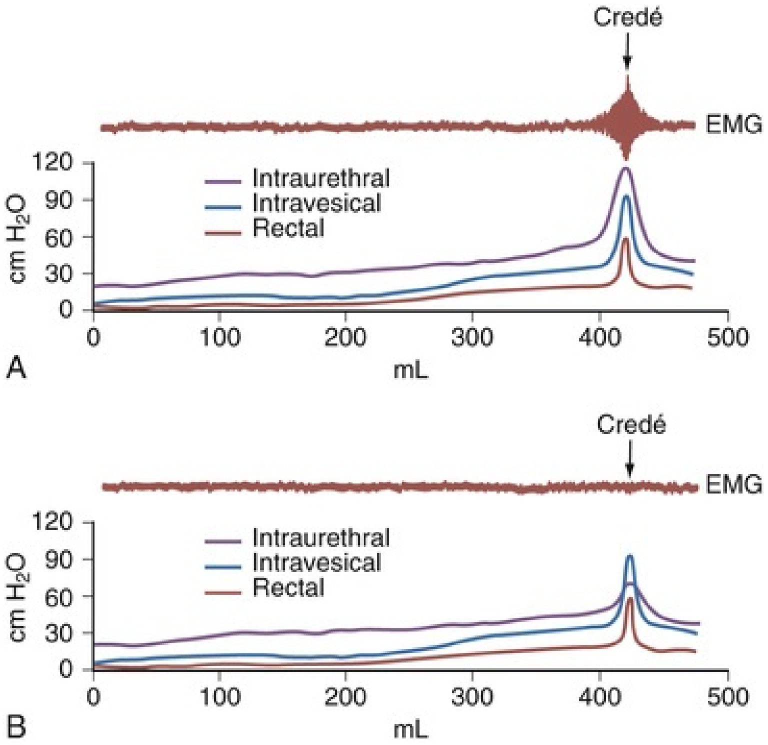

FIG. 34.8 When the external sphincter is reactive (A), the Credé maneuver produces a reflex increase in electromyographic (EMG) activity of the sphincter and a concomitant rise in urethral resistance, resulting in high voiding pressure. A child whose sphincter is denervated and nonreactive (B) will not have a corresponding rise in EMG activity, urethral resistance, or voiding pressure. The Credé maneuver here will not be detrimental. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, ed. *Urologic surgery in neonates and young infants.* Philadelphia, PA: WB Saunders; 1988:252–264.)

The indications for antireflux surgery in this group of children are not very different from those applicable to children with normal bladder function. They include recurrent symptomatic (febrile) urinary infection while receiving adequate antibiotic therapy and appropriate catheterization techniques; persistent hydroureteronephrosis despite effective emptying of the bladder and lowering of intravesical pressure; and severe reflux with an anatomic abnormality at the ureterovesical junction.

Jeffs et al. were the first to show that **antireflux surgery can be very effective in children with neurogenic bladder dysfunction as long as it is combined with measures to ensure complete bladder emptying** (Jeffs et al., 1976). Before this observation was made, the results of ureteral reimplantation were so dismal that most physicians treating these children advocated urinary diversion as a means of managing reflux (Cass, 1976; Smith, 1972). Since the advent of CIC, success rates for antireflux surgery have approached 95% (Kaplan and Firlit, 1983; Kass and Koff, 1981; Woodard et al., 1981). Bilateral surgery for unilateral disease need not be done, because contralateral reflux does not occur postoperatively (Bauer, 1984).

In patients with low-grade reflux who are undergoing augmentation cystoplasty, most clinicians have found acceptable resolution rates of VUR without ureteral reimplantation (Helmy and Hafez, 2013; López Pereira et al., 2001; Morioka et al., 1998). However, for those with dilating reflux (grades 3 and greater), augmentation cystoplasty alone reveals persistence of VUR ranging from 20% to 47% (Helmy and Hafez, 2013; Morioka et al., 1998; Wang et al., 2011). Thus, children with dilating grade reflux who are undergoing augmentation cystoplasty should have concurrent ureteral reimplantation (Helmy and Hafez, 2013; Morioka et al., 1998; Wang et al., 2011).

The endoscopic injection of various materials has altered the management of reflux in children with myelomeningocele (Schlussel, 2004). Success rates of 73% with one injection and 91% with two injections have been reported for the endoscopic management of VUR in those with neurogenic bladder dysfunction (Estornell Moragues et al., 2008; Misra et al., 1996). It has been suggested that success rates of endoscopic therapy in children with neurogenic bladder does not differ from those with a normal bladder (Routh et al., 2008). Higher success rates, approaching 95% have been noted when endoscopic treatment of VUR is paired with intravesical injection of BTA (Neel, 2010; Neel et al., 2008).

However, the durability of this approach has been questioned, with one study showing 40% of those with initial success with endoscopic management had VUR recur at a mean of 4.5 years after the initial treatment (Polackwich et al., 2012). Studies comparing the effectiveness of open surgical to endoscopic management in this population show a significantly greater success rate for traditional open procedures (84.3% to 95.5% vs. 61% to 72.5%) (Engel et al., 1997; Granata et al., 1999). Thus, the endoscopic approach is a reasonable alternative to ureteroneocystotomy; however, long-term outcomes raise concerns about its durability in those with neurogenic bladder dysfunction.

Key Points: Management of Vesicoureteral Reflux

- Low-grade reflux in patients who are emptying well without outlet resistance can be managed with antibiotic prophylaxis alone.

- Patients with high-grade reflux or those who do not empty well also require CIC.
- Patients with poor compliance with or without hydronephrosis should be started on antimuscarinics.
- The Credé maneuver is contraindicated in patients with reflux who have a reactive external urethral sphincter.
- Indications for antireflux surgery are similar to those for children without neurogenic bladder. Success rates are similar if effective bladder emptying is addressed.

Lipomeningocele and Other Spinal Dysraphisms

Presentation

There is a group of congenital defects that affect the formation of the spinal column but do not result in an open vertebral canal (Table 34.7). They occur in 1 in 4000 live births, but with the ease of MRI screening of children with suspected lesions, the detected incidence of these defects is increasing (Bruce and Schut, 1979). The incidence of lipomeningocele in families was calculated to be 0.043% (Sebold et al., 2005). These lesions can be very subtle and have no obvious outward signs, but in more than 90% of children there is a cutaneous abnormality overlying the lower spine (Anderson, 1975; Pierre-Kahn et al., 1997). This varies from a small dimple or skin tag to a tuft of hair, a dermal vascular malformation, a very noticeable subcutaneous lipoma, or an asymmetrically curving gluteal cleft (Fig. 34.9). In addition, on careful inspection of the legs, one may note a high arched foot or feet; hammer or claw toes; a discrepancy in muscle size, leg length, and decreased strength in one leg compared with the other, typically at the ankle; and/or a gait abnormality, especially in older children (Dubowitz et al., 1965; Jindal and Mahapatra, 2000; Weissert et al., 1989). Absent perineal sensation, back pain, and secondary incontinence after a period of dryness are common symptoms in older children and young adults (Linder et al., 1982; Weissert et al., 1989; Yip et al., 1985). LUT function is abnormal in 40% to 90% of affected older individuals, with the incidence of an abnormality increasing proportionately with age (Koyanagi et al., 1997; Mandell et al., 1980; Pierre-Kahn et al., 1997; Sarica et al., 2003). The child may experience difficulty with toilet training, urinary incontinence after an initial period of dryness once toilet trained (especially during the pubertal growth spurt), recurrent urinary infection, and/or fecal soiling. Occasionally, some patients without an obvious back lesion escape detection until they develop urinary (66%) or lower extremity (19%) symptoms or back pain (14%) after puberty caused by delayed traction on the spinal cord (Satar et al., 1995).

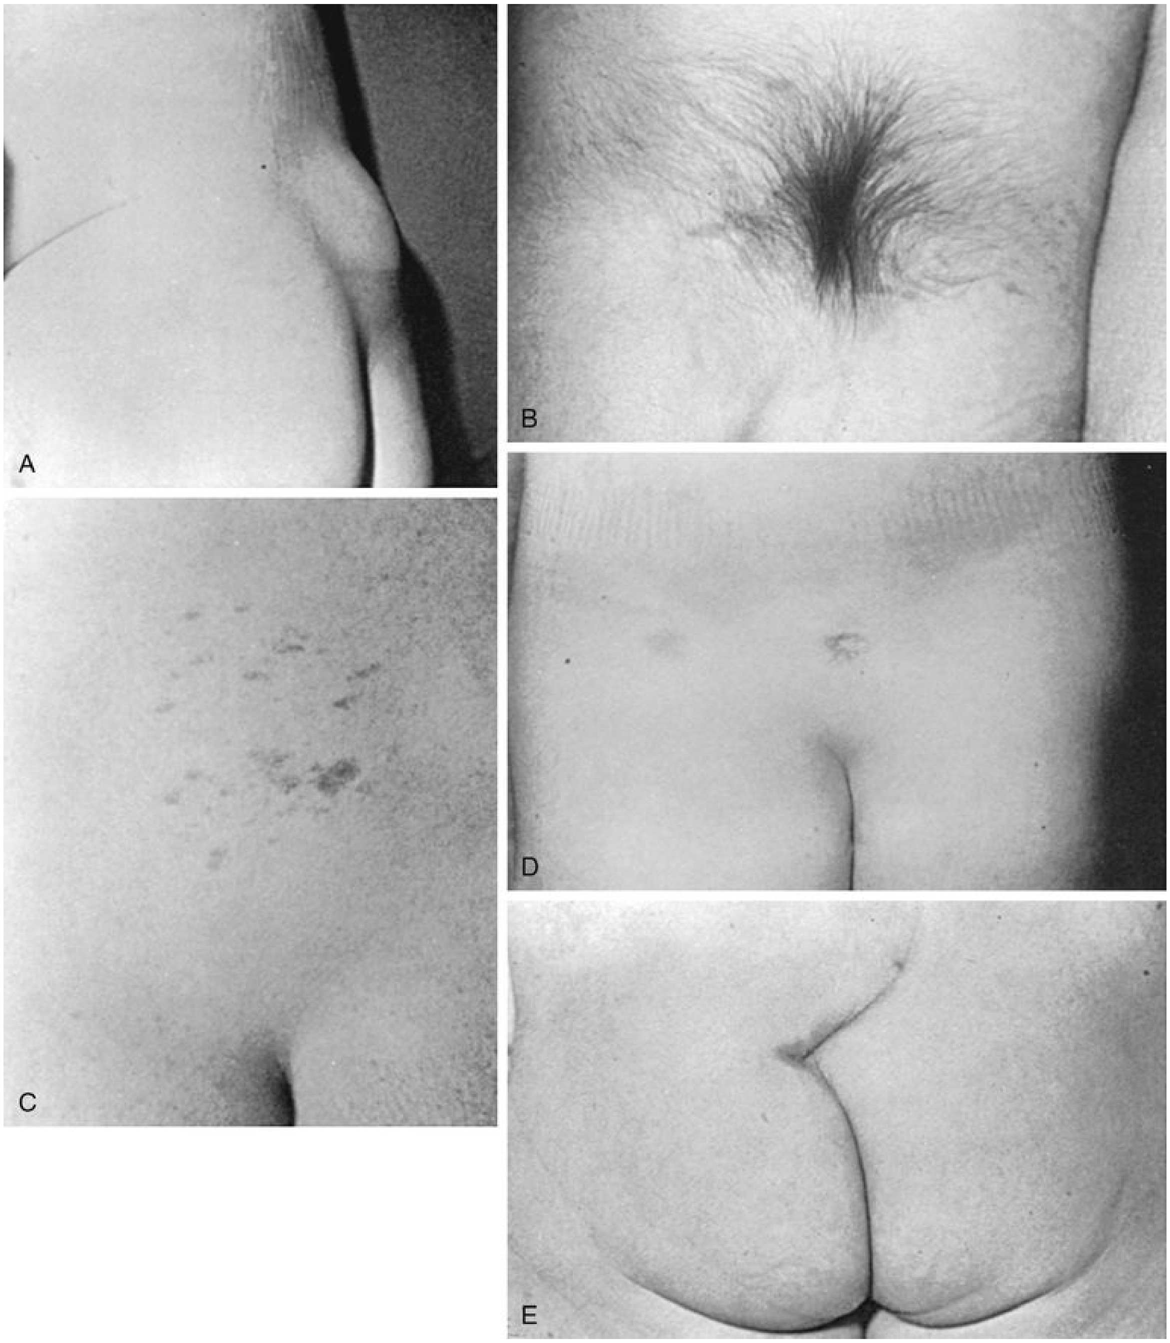

FIG. 34.9 Cutaneous lesions occur in 90% of children with various occult dysraphic states. These lesions vary from a small lipomeningocele (A) to a hair patch (B), a dermal vascular malformation (C), a dimple (D), or an abnormal gluteal cleft (E).

When these children are evaluated in the neonatal period or early infancy, **a majority have a perfectly normal neurologic examination** (Atala et al., 1992). Urodynamic testing, however, reveals abnormal LUT function in about one-third of infants younger than 18 months of age (Keating et al., 1988) (Fig. 34.10). Such studies may provide the only evidence of a neurologic injury involving the lower spinal cord (Atala et al., 1992; Foster et al., 1990; Keating et al., 1988; Nogueira et al., 2004; Satar et al., 1995). When present, the most likely abnormality is an upper motor neuron lesion characterized by an overactive detrusor and/or hyperactive sacral spinal cord reflexes (Fone et al., 1997; Pierre-Kahn et al., 1997); mild forms of DSD are rarely noted. Lower motor neuron signs with denervation potentials in the sphincter or an acontractile detrusor occur in only 10% of young children.

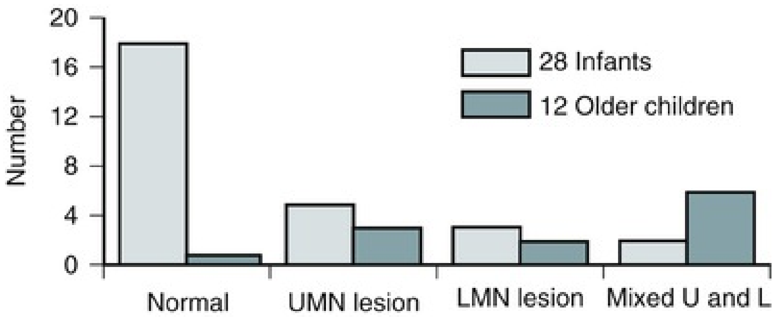

FIG. 34.10 Most neonates with occult spinal dysraphism have normal lower urinary tract function, whereas older children tend to have both upper motor neuron *(UMN)* and lower motor neuron *(LMN)* lesions.

In contrast, practically all individuals older than 3 years of age who have not been operated on or in whom an occult dysraphism has been belatedly diagnosed have either an upper or lower motor neuron lesion or a combination thereof on UDS (92%) (see Fig. 34.10) or neurologic signs of lower extremity dysfunction (Atala et al., 1992; Keating et al., 1988; Kondo et al., 1986; Nogueira et al., 2004; Satar et al., 1995; Yip et al., 1985). When such children were observed expectantly from infancy after the diagnosis was made, 58% experienced deterioration of their disorder within 2 years (Andar et al., 1997; Cornette et al., 1998). There does not seem to be a preponderance of one type of lesion over another (i.e., upper vs. lower motor neuron), and often the child shows signs of both (Hellstrom et al., 1986; Kondo et al., 1986). In one study of children older than 3 years of age, 43% had denervation in the sphincter and 52% had an acontractile detrusor, with a total of 81% having an abnormality (Satar et al., 1995).

Pathogenesis

Various occult spinal dysraphic lesions produce different neurourologic findings. When they do cause an abnormality, lipomas of the cauda equina invariably cause an upper motor neuron lesion (70%), alone or in combination with a lower motor neuron deficit (30%) (Satar et al., 1995). The split cord syndrome results in an isolated upper or lower motor neuron lesion in 25% each or a combined lesion in 50% (Proctor et al., 2000).

The reason for this difference in neurologic findings may be related to (1) compression of the cauda equina or sacral nerve roots by an expanding lipoma or lipomeningocele (Yamada et al., 1983)**; (2) tension on the spinal cord from tethering secondary to differential growth rates in the bony vertebrae and neural elements, and the lower end of the cord is held in place by the lipoma or by a thickened filum terminale** (Dubowitz et al., 1965)**; or (3) fixation of the split lumbosacral cord by an intravertebral bony spicule or fibrous band** (Andar et al., 1997; Pang, 1992; Pang et al., 1992). The overt stretching that invariably occurs when there is a forcible flexion and/or extension of the spinal cord with normal movement leads to changes in oxidation/reduction of cytochrome oxidase, most notably in the lumbosacral spinal neurons when there is no intraspinal pathologic process (Henderson et al., 2005; Yamada et al., 1983). Under normal circumstances the conus medullaris ends just below the L2 vertebra at birth and “recedes” upward to T12 by adulthood (Barson, 1970). When the cord does not “rise” or is fixed in place as a result of one of these lesions, ischemic injury may ensue (Yamada et al., 1981, 2004). Correcting the lesion in infancy has resulted not only in stabilization but also in improvement in the neurologic picture in many instances (Cornette et al., 1998; Koyanagi et al., 1997; Proctor et al., 2000) (Fig. 34.11). Sixty percent of infants with abnormal urodynamic findings preoperatively revert to normal postoperatively, with improvement noted in 30%; 10% become worse with time. In older children there is a less dramatic change after surgery, with only 27% becoming normal, 27% improving, 27% stabilizing, but 19% actually becoming worse with time (see Fig. 34.11) (Keating et al., 1988; Satar et al., 1995). Older children with an overactive detrusor tend to improve, whereas those with acontractile bladders do not (Flanigan et al., 1989; Hellstrom et al., 1986; Kondo et al., 1986). Finally, 5% to 27% of children operated on in early childhood develop secondary tethering when observed for several years, suggesting that early surgery has both beneficial and sustaining effects in patients with this condition (Pierre-Kahn et al., 1997; Proctor et al., 2000; Satar et al., 1995).

FIG. 34.11 The potential for recoverable function is greatest in infants (6 of 10, 60%) and less so in older children (3 of 11, 27%). The risk for damage to neural tissue at the time of exploration to those with normal function is small (2 of 19, 11%). *UDS,* Urodynamic study.

As a result of these findings, it is apparent that urodynamic testing may be the only way to document that an occult spinal dysraphism is actually affecting lower spinal cord function (Keating et al., 1988; Khoury et al., 1990; Pierre-Kahn et al., 1997; Sarica et al., 2003). The serial use of electromyography of the external urethral sphincter using a needle electrode to monitor individual motor unit action potentials provides a precise mechanism for measuring changes in innervation that may occur over time. Some investigators have shown that posterior tibial somatosensory evoked potentials are an even more sensitive indicator of tethering and should be an integral part of the urodynamic evaluation (Roy et al., 1986). The implication of these findings lies in the fact that **early detection and early intervention can either reverse or at least stabilize the progression of the lesion, which does not happen in older children** (Kaplan et al., 1988; Yamada et al., 1983), and offers a degree of protection from subsequent tethering (Pierre-Kahn et al., 1997; Proctor et al., 2000; Satar et al., 1995), which seems to be a frequent occurrence when the lesion is not dealt with expeditiously in infancy (Chapman, 1982; Seeds and Jones, 1986) (see Fig. 34.11). Improvement of urodynamic parameters is most likely to occur in those undergoing neurosurgical repair for lipomeningocele in the first 12 months of life compared with those 12 to 36 months of age. Those children undergoing surgery after 36 months of age were least likely to have improvement in their urodynamic findings (Rendeli et al., 2007). Thus, early intervention provides more favorable outcomes for motor and bladder function (Tuite et al., 2016).

Specific Recommendations

In addition to MRI studies (Tracy and Hanigan, 1990), urodynamic testing including EMG of the external urethral sphincter should be performed in every child who has a questionable cutaneous or bony abnormality of the lower spine, especially if there is a radiologic abnormality of the spinal cord (Campobasso et al., 1988; Hall et al., 1988; Meyrat et al., 2003; Packer et al., 1986). This test provides the most accurate measure of sacral spinal cord function at diagnosis and provides a basis for comparison with subsequent studies when the children are either operated on or carefully observed. **In children younger than 3 months of age, the vertebral bones have not ossified; thus a window of opportunity exists for ultrasonography to be a useful screening tool in visualizing the spinal canal** (Fig. 34.12) (Raghavendra et al., 1983; Scheible et al., 1983)**. At this age, there is good correlation between the ultrasound imaging and MRI findings; however, if a spinal cord abnormality is identified, the latter provides a better definition of the spinal cord lesion. Consequently, ultrasonography should not be used as the definitive imaging modality** (Hughes et al., 2003). Older children with an occult spinal cord lesion may have urologic symptoms in 20% of cases (Hsieh et al., 2006), and 50% to

60% may have abnormal urodynamic findings preoperatively (Guerra et al., 2006). Resolution of abnormal urodynamic parameters is noted in 50% to 60% of cases after detethering (Guerra et al., 2006; Hsieh et al., 2006). **Therefore, urodynamic testing is recommended for all children with an occult spinal dysraphism before and after spinal cord detethering procedures.** In addition to UDS, all children should have renal/bladder ultrasonography at presentation (Bauer et al., 2012).

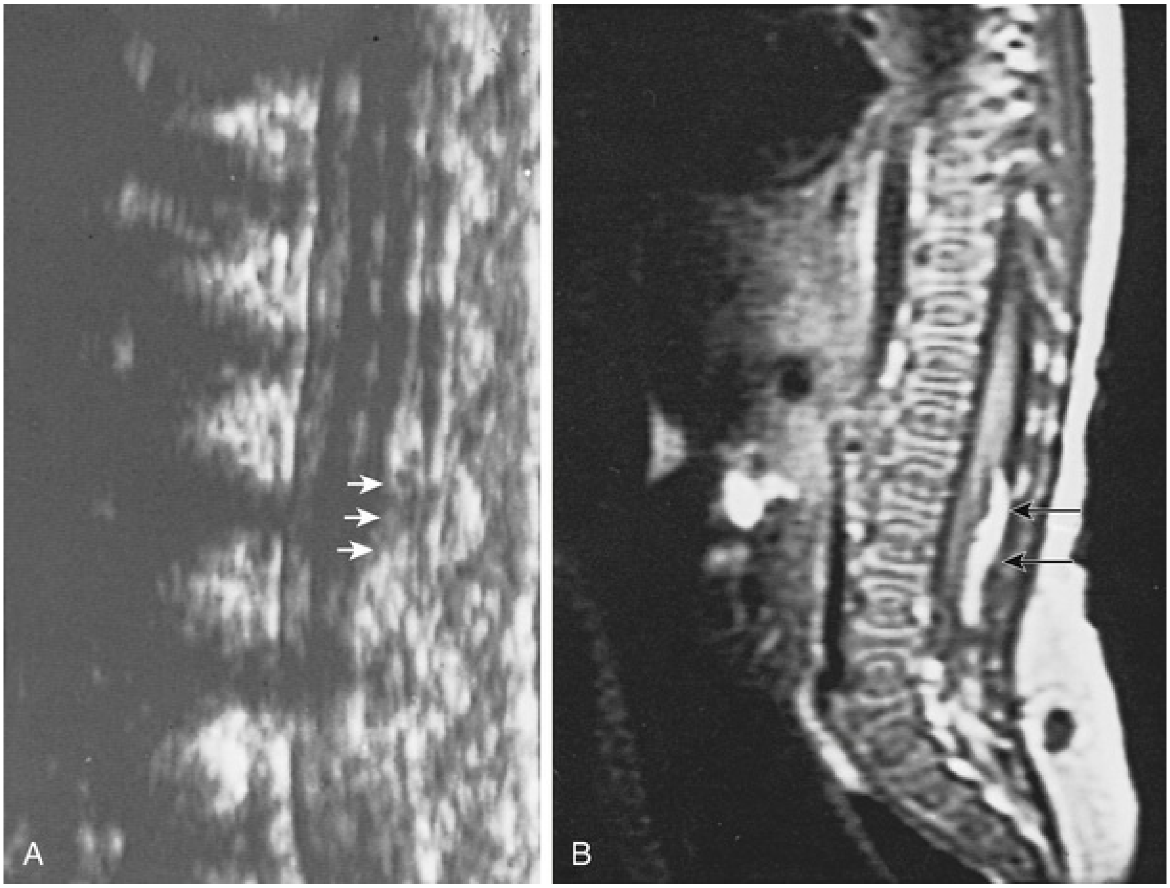

FIG. 34.12 (A) During the first few months of life, ultrasonography can clearly demonstrate intravertebral anatomy because the posterior arches have not completely ossified. Note that the spinal cord along with its central canal is displaced anteriorly *(white arrows)* beginning at L3 because of an intradural lipoma. (B) The MRI scan is juxtaposed to confirm the ultrasound findings. The longitudinal white intraspinal mass *(black arrows)* is the lipoma; the longitudinal gray mass is the spinal cord.

In the past, most of these conditions were treated by excising the superficial skin lesion without dissecting further into the spinal canal to remove or repair the entire abnormality. Currently, most neurosurgeons advocate laminectomy and removal of the intraspinal process as completely as possible without injuring the nerve roots or cord to release the tether and prevent further injury with subsequent growth (Atala et al., 1992; Foster et al., 1990; Kaplan et al., 1988; Kondo et al., 1986; Linder et al., 1982; Pierre-Kahn et al., 1997; Proctor et al., 2000). Long-term urologic follow-up is recommended, according to the guidelines put forth by the ICCS, which are summarized in Table 34.3 (Bauer et al., 2012).

Key Points: Lipomeningocele and Other Spinal Dysraphisms

- Children with an occult neural tube defect often present after 3 or 4 years of age with incontinence or constipation. They may present with new urologic symptoms after a growth spurt related to tethering of the spinal cord. Most have a cutaneous abnormality overlying the spine.
- Radiologic examination of the spine, MRI, and renal ultrasonography are indicated in the initial evaluation. Spinal ultrasonography may be used as a screening investigation before MRI in those younger than 3 months of age.
- UDS should be done before and after spinal cord detethering.
- Intervention with spinal cord detethering early in life is associated with more favorable outcomes than when done later.

Sacral Agenesis

Presentation

Sacral agenesis has been defined as the absence of part or all of two or more lower vertebral bodies. The presentation is bimodal, with more than three-fourths of children being detected in early infancy and the remainder discovered between 4 and 5 years of age (Wilmshurst et al., 1999). With the increased use of prenatal ultrasonography, it is being diagnosed with increased frequency before birth. Sacral vertebral bony ossification begins at 15 weeks, so it is possible to detect the lesion after 18 weeks' gestation on a prenatal ultrasound examination and then to confirm it by fetal MRI (De Biasio et al., 2003). When not detected prenatally or at birth, the diagnosis is often delayed until failed attempts at toilet training bring the child to the attention of a physician. Presenting urinary symptoms in those 4 years of age and older include urinary incontinence or constant dribbling in 85% and recurrent UTI in 74%. VUR may be seen in up to 65% (Emami-Naeini et al., 2012). Sensation, including that in the perianal dermatomes, is usually intact, and lower extremity function is normal (Capitanucci et al., 1997; Koff and Deridder, 1977). Because these children have normal sensation and little or no orthopedic deformity in the lower extremities (although high arched feet or claw toes or hammer toes may be present), the underlying lesion is often overlooked. In fact, 20% escape detection until 3 or 4 years of age (Guzman et al., 1983). The only clue, besides a high index of suspicion, is flattened buttocks and a low, short gluteal cleft (Bauer, 1990) (Fig. 34.13). Palpation of the coccyx is helpful in detecting the absent vertebrae (White and Klauber, 1976). The diagnosis is most easily confirmed with a lateral film of the lower spine, because this area is often obscured by overlying gas and fecal matter on an anteroposterior projection (Guzman et al., 1983; White and Klauber, 1976) (Fig. 34.14). MRI has been used to visualize the spinal cord in these cases; its imaging reveals a sharp cutoff of the conus at T12 as a consistent finding (Diel et al., 2001; Pang, 1993) (Fig. 34.15).

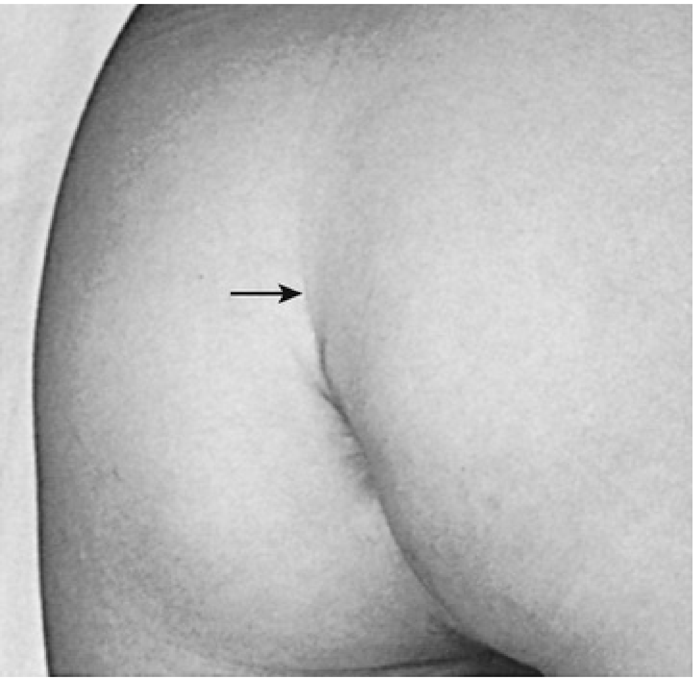

FIG. 34.13 Characteristically, in sacral agenesis the gluteal crease is short and is seen only inferiorly *(below arrow)* because of the flattened buttocks.

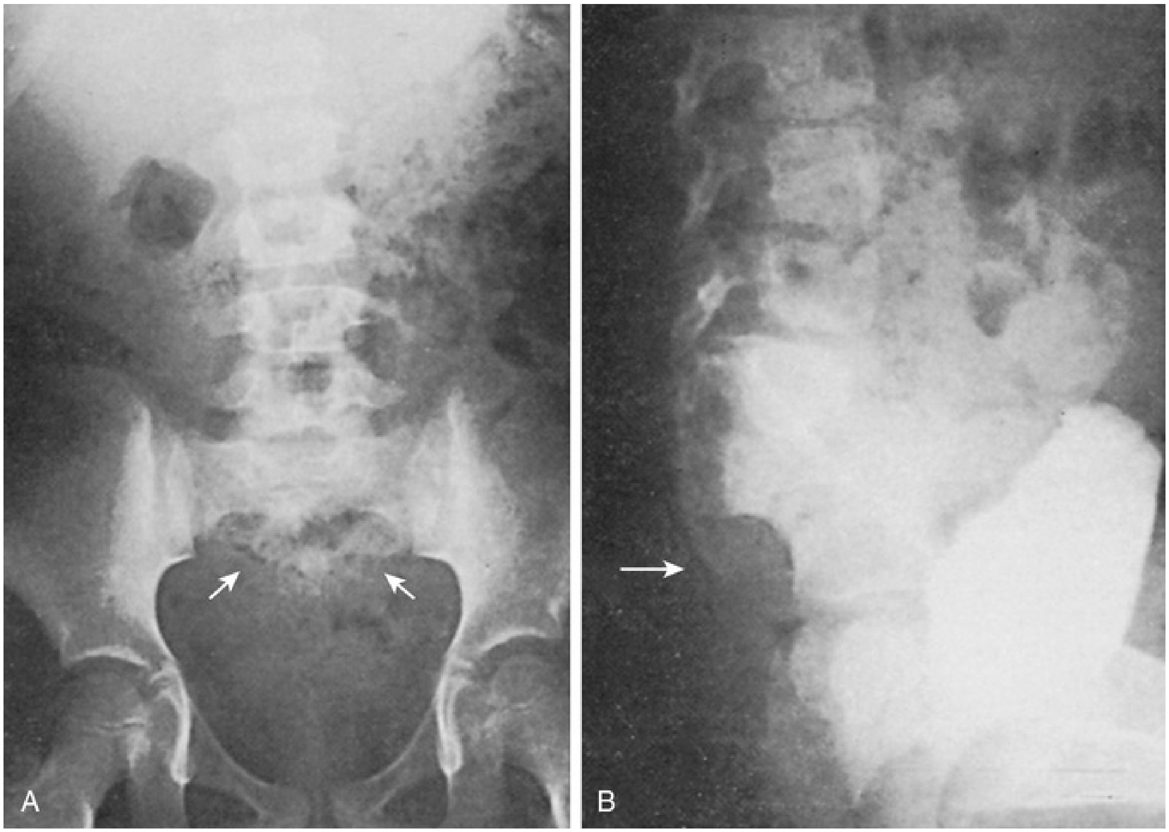

FIG. 34.14 The diagnosis of partial or complete sacral agenesis *(arrows)* is easily confirmed on an anteroposterior (A) or lateral (B) radiograph of the spine if bowel gas obscures the sacral area. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, ed. *Urologic surgery in neonates and young infants.* Philadelphia, PA: WB Saunders; 1988:283–310.)

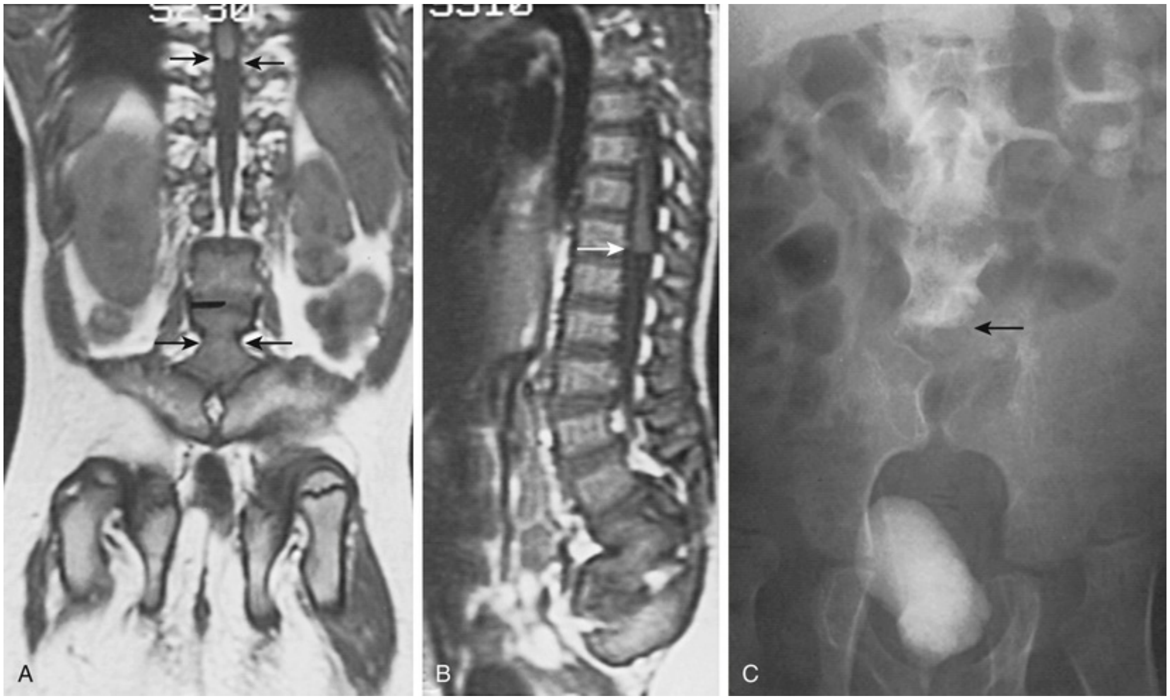

FIG. 34.15 Coronal (A) and sagittal (B) MRI scan in a 10-year-old boy with sacral agenesis beginning at L5. Note the squared lower limit of the cord adjacent to T11 (A, *upper arrows;* B, *white arrow*) and the two sacroiliac joints (A, *lower arrows*), which are in the midline because of absence of the sacrum. (C) An anteroposterior radiograph from an excretory urogram shows no vertebral bodies below L4 *(arrow).*

On urodynamic evaluation, an almost equal number of individuals manifest either an upper or lower motor neuron lesion (35% vs. 40%, respectively); 20 to 25% have no sign of denervation (Boemers et al., 1994a; Guzman et al., 1983). The number of affected vertebrae does not seem to correlate with the type of motor neuron lesion present (Boemers et al., 1994a) (Fig. 34.16). The injury appears to be stable and rarely shows signs of progressive denervation as the child grows. Sacral sensation is relatively spared, even in the presence of extensive sacral motor deficits (Boemers et al., 1994a). UTI may be detected in 75% of children over time, with VUR diagnosed in 37%. Reflux is most likely to occur in those with an upper motor neuron lesion (75%) (irrespective of whether they have synergy or dyssynergy) versus a lower motor neuron lesion (40%) (Wilmshurst et al., 1999).

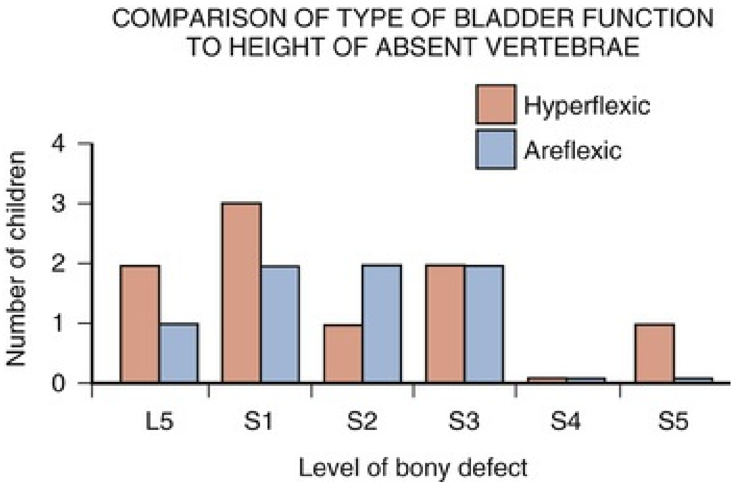

FIG. 34.16 Bladder contractility is unrelated to the number of absent vertebrae. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, ed. *Urologic surgery in neonates and young infants.* Philadelphia, PA: WB Saunders; 1988:283–310.)

Pathogenesis

The cause of this condition is still uncertain, but teratogenic factors may play a role, because insulin-dependent diabetic mothers have a 1% chance of giving birth to a child with this disorder. Conversely, 16% or more of children with sacral agenesis have a mother who is insulin dependent with diabetes mellitus (Guzman et al., 1983; Passarge and Lenz, 1966; Wilmshurst et al., 1999). In cases of gestational insulin-dependent diabetes, this dependency is present before conception or begun early in the first trimester. The disease has been reproduced in chicks by exposing embryos to insulin (Landauer, 1945; White and Klauber, 1976). Maternal insulin-antibody complexes have been noted to cross the placenta, and their concentration in the fetal circulation is directly correlated with macrosomia (Menon et al., 1990). It is possible that a similar cause-and-effect phenomenon occurs in sacral agenesis. There is evidence that a deletion of the seventh chromosome (7q36) leading to the absence of a transcription factor may be responsible for this anomaly (Papapetrou et al., 1999). In addition, maternal drug exposure (i.e., minoxidil) has been reported to cause sacral agenesis (Rojansky et al., 2002).

In familial cases of sacral agenesis associated with the Currarino syndrome (presacral mass, sacral agenesis, and anorectal malformation), deletions in chromosome 7 (7q) resulting in *HLXB9* genetic mutations have been found (Ross et al., 1998). A mutation in *HLXB9*, a homeodomain gene of a 403–amino acid protein that appears to be responsible for neural plate infolding, has been identified in 20 of 21 patients with familial cases and in 2 of 7 sporadic cases of Currarino syndrome (Hagan et al., 2000; Köchling et al., 2001). Heterozygote carriers within these families have also been identified (Lynch et al., 2000). Thus, sacral agenesis may represent one point on a spectrum of abnormalities that encompass sacral meningoceles and anorectal malformations (Bernbeck et al., 2004).

Specific Recommendations

Because most children who are diagnosed with this condition have a neurologic deficit, urodynamic testing is mandatory at the time of diagnosis. **Renal ultrasonography and nuclear or conventional cystography should be included as part of the evaluation process, especially if the child has a history of UTI or findings of an upper motor neuron lesion on urodynamic testing.** Additional imaging studies may be required based on the child's history and findings from baseline studies.

Management depends on the specific type of neurourologic dysfunction seen on urodynamic testing (Choi et al., 2016). Antimuscarinic agents should be given to children with upper motor neuron findings of detrusor overactivity, whereas CIC and α-sympathomimetic medications may have to be given to individuals with lower motor neuron deficits who cannot empty their bladders or stay dry between catheterizations. When antimuscarinic medication is ineffective in controlling the overactive detrusor, augmentation cystoplasty may be required to attain an adequate organ for urinary storage. Failure of α-sympathomimetic agents may require either endoscopic injection of bulking agents, AUS implantation, bladder neck sling, or bladder neck reconstruction with or without bladder neck sling to increase bladder outlet resistance. The bowels manifest a similar picture of dysfunction and need as much characterization and treatment as the LUT. Anorectal manometry has identified abnormalities in the internal anal sphincter and in voluntary anal sphincter squeeze pressure, leading to weakness of the muscle and concomitant fecal incontinence (Morera and Nurko, 2003). It is important to identify these individuals as early as possible so that they can become continent and out of diapers at an appropriate age, thus avoiding the social stigma of fecal or urinary incontinence.

Key Points: Sacral Agenesis

- The index of suspicion for sacral agenesis should be high in children presenting with incontinence or UTIs with a short gluteal cleft and/or flattened buttocks.
- The children of diabetic mothers or those with gestational diabetes are at increased risk.
- Initial investigation includes UDS, renal ultrasonography, and nuclear cystography.
- Long-term follow-up is required.

Conditions of the Pelvis

Anorectal Malformations

Presentation

Anorectal malformations encompass a wide spectrum of diseases involving the distal anus and rectum and the urinary and genital tracts. The abnormalities may be minor with excellent prognosis or very complex with poor functional outcomes (Levitt and Peña, 2007). This malformation occurs in approximately 1 in 5000 live births (Levitt and Peña, 2007). The International (Krickenbeck) Classification of anorectal malformations separates entities into major clinical groups according to the location of fistula and rare or regional variants (Table 34.8) (Holschneider et al., 2005). Urinary tract abnormalities have been noted in 26% to 52% of affected children, with renal agenesis (primarily left-sided) and VUR as the most common associated findings (Parrott, 1985). The highest incidence of an abnormality is in those children with a high (70%) (supralevator insertion of fistula) versus a low (infralevator) (35%) lesion (Emir and Söylet, 1998; Shaul and Harrison, 1997), with boys more prone than girls to having an anomaly (50% vs. 29%) (Metts et al., 1997).

TABLE 34.8

Types of Occult Spinal Dysraphisms

Lipomeningocele
Intradural lipoma
Diastematomyelia
Tight filum terminale
Dermoid cyst/sinus
Aberrant nerve roots
Anterior sacral meningocele

Spinal bony abnormalities range in incidence from 30% to 44%, but patients with a high lesion are more likely to be affected (48% to 54%) than those with a low lesion (15% to 27%) (Carson et al., 1984; Long et al., 1996; Tsakayannis and Shamberger, 1995). Spinal cord abnormalities including tethered cord, thickened or fatty filum terminale, and lipoma have been noted in 18% to 50% of patients, with the incidence varying proportionately in relation to the height of the rectal lesion (Shaul and Harrison, 1997). Neurogenic bladder dysfunction is a frequent finding (Kakizaki et al., 1994), usually manifesting as incontinence, but its occurrence is rare when no spinal cord malformation exists (Hulthén de Medina et al., 2004) (Fig. 34.17). It often manifests when the child is older and the parents have difficulty with toilet training. Cutaneous malformations suggesting an underlying occult spinal dysraphism is rarely, if ever, present.

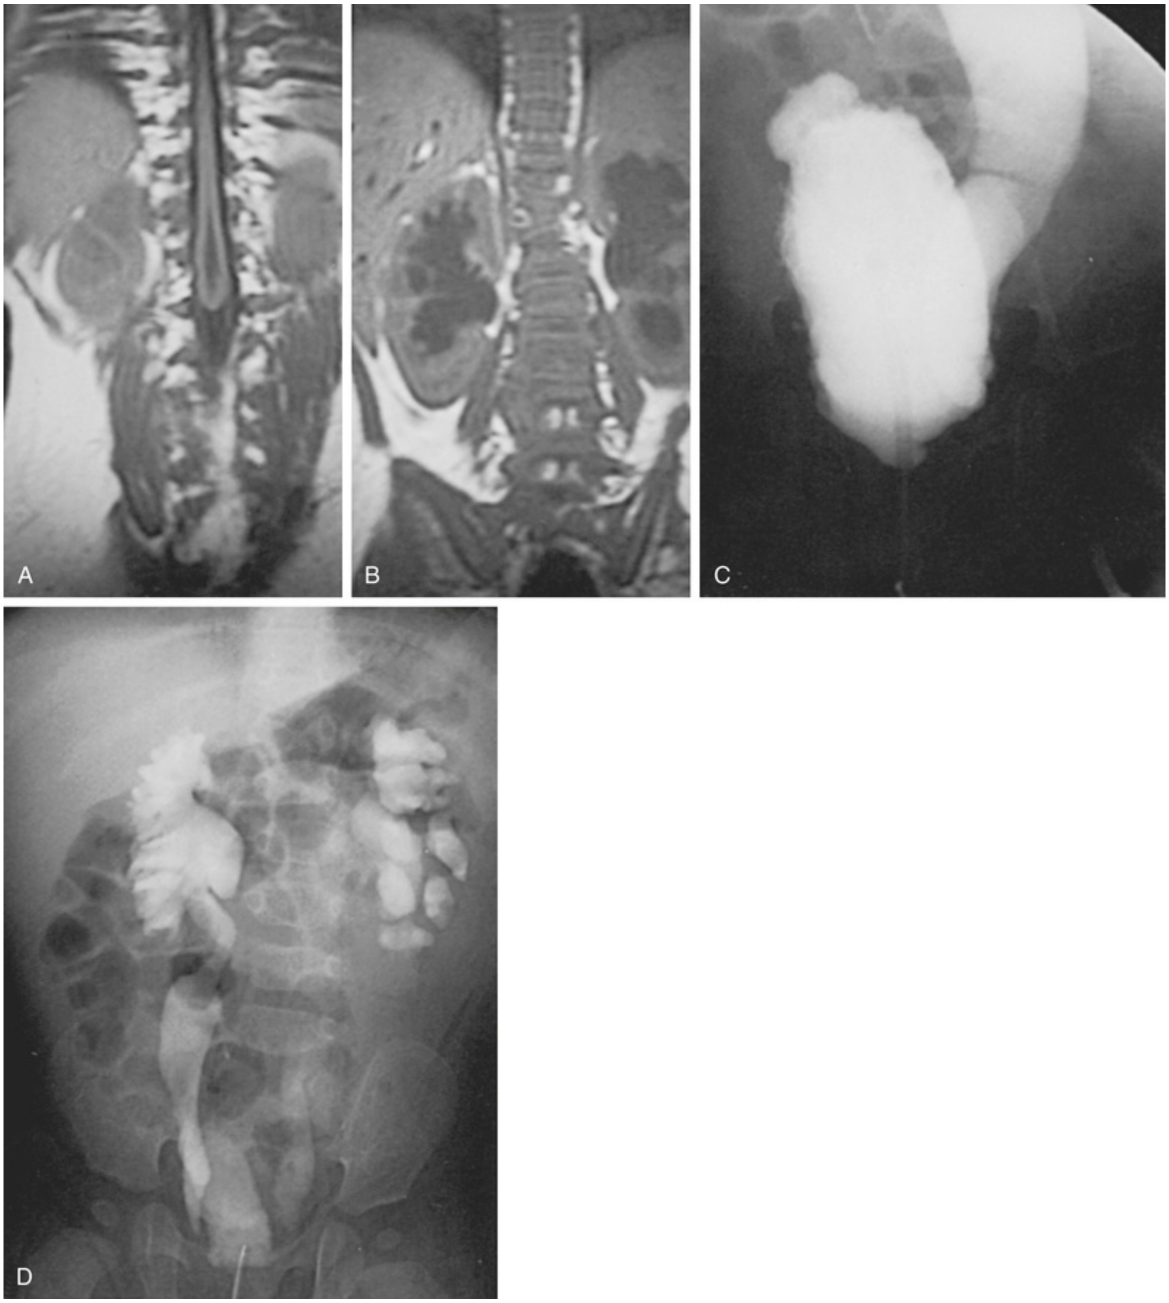

FIG. 34.17 (A, B) A 1-year-old girl with an imperforate anus and bony vertebral abnormalities has a tethered cord and bilateral hydronephrosis on magnetic resonance imaging. (C) Voiding cystourethrogram reveals significant trabeculation and reflux on the left. (D) Excretory urogram demonstrates bilateral hydronephrosis secondary to the reflux on the left and a ureterovesical junction obstruction on the right. Subsequent urodynamic study revealed poor detrusor compliance and dyssynergy.

Anorectal malformations may be nonsyndromic or occur in conjunction with many different conditions (Levitt and Peña, 2007). Important examples of syndromic anorectal malformations include VACTERL syndrome (**v**erterbral anomalies, **a**nal atresia, **c**ardiac malformations, **t**racheo**e**sophageal fistula, **r**enal anomalies, and **l**imb abnormalities), MURCS (**Mü**llerian duct aplasia, **r**enal aplasia, and **c**ervicothoracic **s**omite dysplasia), OEIS (**o**mphalocele, **e**xstrophy, **i**mperforate anus, and **s**pinal defects), and Currarino syndrome (anorectal malformation, sacrococcygeal defect, presacral mass) (Currarino et al., 1981; Levitt and Peña, 2007).

The most common finding on urodynamic testing is an upper motor neuron lesion with an overactive detrusor and/or DSD (Boemers et al., 1994b; Borg et al., 2009; Taskinen et al., 2002) but a lower motor neuron lesion with an acontractile detrusor and a denervated sphincter may be seen as well (see Fig. 34.17) (Greenfield and Fera, 1991; Taskinen et al., 2002). Leak point pressures in excess of 40 cm H_2O, decreased compliance, and low bladder capacity has been noted (De Filippo et al., 1999; Stathopoulos et al., 2012). Normal UDS do not exclude a vertebral anomaly or spina bifida (Stathopoulos et al., 2012).

Children with Currarino syndrome are noted to have a tethered spinal cord in more than 80% of cases (Lee et al., 2012a). Postoperative voiding complaints including urgency, frequency, incontinence, and UTI are noticed in approximately 80% (Lee et al., 2012a). Upper urinary tract changes such as hydronephrosis and VUR are not uncommon (Lee et al., 2012a). Surgical untethering of the spinal cord results have variable outcomes for urodynamic abnormalities, with some showing improvement, worsening, or no change (Lee et al., 2012a). Urodynamic abnormalities include small capacity, poor compliance, detrusor overactivity, detrusor sphincter dyssynergia, and/or high voiding pressure (Lee et al., 2012a).

Pathogenesis

The etiology of anorectal malformations remains unclear. It is most likely multifactorial, with some genetic component (Levitt and Peña, 2007). Although evidence for risk factors in the development of anorectal malformations is limited, paternal smoking, maternal obesity, and maternal pregestational and gestational diabetes are associated with increased risk (Zwink et al., 2011). **The etiology of neurogenic bladder in these children is most commonly associated with a spinal cord abnormality.** The posterior sagittal anorectoplasty (PSARP) approach espoused by Peña (1986) minimizes the chances of injuring the pelvic nerves that innervate the pelvic floor muscles and does not appear to result in iatrogenic neurogenic bladder dysfunction (Borg et al., 2009; De Filippo et al., 1999). Eighteen percent to 35% of those with anorectal malformations are noted to have neurogenic bladder (Borg et al., 2009; Mosiello et al., 2003a; Stathopoulos et al., 2012). Almost all have abnormal urodynamic findings before PSARP (Borg et al., 2009) and are usually (Borg et al., 2009) but not always (De Filippo et al., 1999; Stathopoulos et al., 2012) associated with a spinal cord abnormality.

Specific Recommendations

Initial evaluation in the neonatal period should include careful inspection of the perineum looking for a fistulous site from the bowel, an examination of the upper and lower extremities, and an assessment of the spine and spinal cord (Carson et al., 1984; Mosiello et al., 2003a). Because of the high rate of associated genitourinary abnormalities, **renal-bladder ultrasonography is indicated in all children with an anorectal malformation** (Levitt and Peña, 2007). Abnormalities of the renal ultrasound scan such as hydronephrosis and renal asymmetry should be further investigated with VCUG.

Not all patients with a spinal cord abnormality have a bony defect, so intraspinal imaging in all children with anorectal malformations is recommended to ensure the presence of a normal spinal cord. (Miyasaka et al., 2009; Mosiello et al., 2003a; Rivosecchi et al., 1995). To rule out any abnormal intraspinal process, ultrasonography of the spine in children younger than 3 months of age (because the vertebral bodies have not ossified) or spinal MRI in those older than 3 months of age is recommended (see Figs. 34.12 and 34.17) (Barnes et al., 1986; Emir and Söylet, 1998; Mosiello et al., 2003a; Tunell et al., 1987).

UDS are reserved for children with either a bony abnormality of the spine, a spinal cord defect, or the telltale signs of dysfunction on VCUG or renal ultrasonography (Mosiello et al., 2003a; Taskinen et al., 2002). These studies should be conducted early in infancy before the child has had any definitive surgery for the imperforate anus and again after a pull-through operation has been performed on the rectum to determine, respectively, the true incidence of neurogenic bladder dysfunction and any changes that might have occurred as a result of the surgery (Borg et al., 2009). The presence of an abnormality on urodynamic testing in early infancy may warrant either intervention at that time to correct a spinal cord defect or watchful waiting to determine whether the lesion is progressive. UDS are repeated subsequently or performed for the first time if secondary urinary or fecal incontinence ensues (Taskinen et al., 2002). Long-term follow-up reveals that ESRD is rare, but may occur in just under 2% of those children with anorectal malformation (Giuliani et al., 2013). Thus, if neurogenic bladder dysfunction is noted, long-term follow-up with annual ultrasonography and repeat urodynamic or other imaging studies as specified in Table 34.3 is recommended.

Pelvic Surgery

Presentation

In children, exenterative pelvic surgery for sacrococcygeal teratoma (Ozkan et al., 2006), pelvic rhabdomyosarcoma/other pelvic neoplasms (Yeung et al., 1994), and Hirschprung disease (Holschneider et al., 2005) is well known to have deleterious effects on LUT function.

Children who have surgical resection of sacrococcygeal teratomas are noted to develop neurogenic bladder dysfunction in 35% to 45% of cases (Gabra et al., 2006; Le et al., 2011). Common presenting symptoms include UTI and incomplete bladder emptying (Ozkan et al., 2006). Urodynamic profiles reveal normal findings in 28% (Ozkan et al., 2006), detrusor overactivity in 57% to 81% (Boemers et al., 1994a; Ozkan et al., 2006), detrusor underactivity in 14% to 27% (Boemers et al., 1994a; Ozkan et al., 2006), poor compliance in 33% (Le et al., 2011), and detrusor sphincter dyssynergia in 18% to 38% (Boemers et al., 1994a; Ozkan et al., 2006). Upper urinary tract deterioration may include renal scarring or decreased GFR (25%) (Le et al., 2011), VUR (25% to 50%) (Le et al., 2011; Ozkan et al., 2006), and hydronephrosis (30% to 43%) (Le et al., 2011; Ozkan et al., 2006). A tethered spinal cord can contribute to the neurogenic bladder abnormality in a small proportion of patients with sacrococcygeal teratoma (Boemers et al., 1994a; Mosiello et al., 2003b).

Children presenting with genitourinary rhabdomyosarcomas in the past were uniformly treated with cystectomy. Currently, bladder preservation is attempted when feasible (Raney et al., 2006). Children who are treated for pelvic neoplasms are noted to have normal bladder function postoperatively in 27% to 40% (Arndt et al., 2004; Hishiki et al., 2013; Mosiello et al., 2003b). Those who are symptomatic with their LUT dysfunction present with nocturnal enuresis (26%) (Raney et al., 2006), daytime incontinence (14% to 27%) (Raney et al., 2006), urinary urgency (Soler et al., 2005), suprapubic pain with bladder filling (Soler et al., 2005), and UTIs (55%) (Raney et al., 2006). UDS reveal markedly reduced functional bladder capacity (Soler et al., 2005; Yeung et al., 1994), detrusor overactivity (Mosiello et al., 2003b; Soler et al., 2005), detrusor underactivity (Mosiello et al., 2003b), and detrusor sphincter dyssynergia (Mosiello et al., 2003b). Those children treated with bladder preservation strategies for pelvic rhabdomyosarcoma, especially those who receive radiation therapy, are at high risk for LUT symptoms and upper urinary tract deterioration (Raney et al., 2006; Soler et al., 2005; Yeung et al., 1994). Abnormal renal function was noted in one-third and hydronephrosis in 15% (Raney et al., 2006). Urinary tract reconstruction or diversion was ultimately required in close to 20% of children in one large series (Raney et al., 2006).

Up to 45% of children with Hirschsprung disease will have unstable detrusor contractions that often resolve after the abnormal bowel is resected (Boemers et al., 2001). Transient urinary retention was noted in up to 7% of children undergoing surgery for Hirschsprung disease (Ateş et al., 2007). From to 0% to 6% of children had urinary incontinence postoperatively with long-term follow-up (Holschneider et al., 1982; Boemers et al., 2001). Approximately one-third of these children had normal urodynamic findings postoperatively (Boemers et al., 2001). Two-thirds had an increased maximum cystometric capacity (Boemers et al., 2001), and 55% to 78% had a high postvoid residual urine (Ateş et al., 2007; Boemers et al., 2001). Poor compliance was rarely noted (Boemers et al., 2001). Different surgical approaches are noted to have varying effects on bladder function (Ateş et al., 2007).

Pathogenesis

Surgery of the pelvic viscera can result in damage to the pelvic splanchnic nerves, the hypogastric nerves, or the pelvic nerve plexus, resulting in autonomic denervation. Parasympathetic denervation (injury to the pelvic splanchnic nerves) may result in an acontractile bladder. Sympathetic denervation (injury to the hypogastric nerves) may cause a loss of bladder compliance and diminished or unresponsive changes in bladder neck resistance when increases in abdominal pressure occur. Mixed patterns of LUT dysfunction may be seen with injury to the pelvic plexus (Blaivas and Barbalias, 1983; Chang and Fan, 1983; Leveckis et al., 1995; Woodside and Crawford, 1980; Yalla and Andriole, 1984).

Specific Recommendations

The risk for upper urinary tract deterioration in those having resection of pelvic sacrococcygeal teratomas is high, therefore preoperative and postoperative UDS are recommended for all (Le et al., 2011; Ozkan et al., 2006). Long-term urologic follow-up is required with annual ultrasonography and clinical review in those who demonstrate urodynamic abnormalities or symptoms. Those who are asymptomatic and/or demonstrate normal postoperative investigations do not require further long-term evaluation unless symptoms arise.

As the risk for upper tract deterioration in those undergoing surgery for pelvic rhabdomyosarcomas is relatively high, it is recommended that all survivors, particularly those who had radiation therapy, be carefully monitored for upper and LUT dysfunction (Yeung et al., 1994). This screening should be carried out with a frequency volume chart (Yeung et al., 1994), with urodynamic and ultrasound investigation limited to those with dysfunction. Long-term urologic follow-up is required with annual ultrasonography and clinical review in those who demonstrate urodynamic abnormalities or symptoms. Those who are asymptomatic and/or demonstrate normal postoperative investigations do not require further long-term evaluation unless symptoms arise.

As children undergoing surgery for Hirschprung disease are usually only symptomatic if bladder function is altered, routine postoperative urodynamic testing is not recommended for everyone. However, all patients should have clinical preoperative and postoperative screening for abnormal LUT function and undergo a urinary tract ultrasound examination (Boemers et al., 2001). Those who are symptomatic preoperatively warrant UDS before surgery. Those who are symptomatic after surgery should have UDS completed 6 months after surgery to allow resolution of temporary neuropraxia (Boemers et al., 2001). Long-term urologic follow-up is required with annual ultrasound examinations and clinical review in those who demonstrate urodynamic abnormalities or symptoms. Those who are asymptomatic and/or demonstrate normal postoperative investigations do not require further long-term evaluation unless symptoms arise.

Central Nervous System Insults

Presentation

CP is the most common physical disability in childhood. A recent study in the United States found that approximately 3.3 of 1000 8-year-old children are variably affected. Its prevalence varies by region. It is more common in black children and white children than in those who are Hispanic, and it is 1.2 times more common in boys than in girls (Kirby et al., 2011). CP is a disorder of the development of movement and posture causing limitations in activities that are the result of nonprogressive disturbances of the fetal or infant brain. Sensation, perception, cognition, communication, and behavior may also be affected (Richards, 2013; Richards and Malouin, 2013) The Gross Motor Function Classification System – Expanded and Revised in 2007 (GMFCS – E&R) (https://canchild.ca/en/resources/42-gross-motor-function-classification-system-expanded-revised-gmfcs-e-r) is based on self-initiated movement, with emphasis on sitting, transferring, and mobility. This is a five-level scale that ranges from 1 (walks without limitations) to 5 (transported in a manual wheelchair). Specific descriptions with relevant age band categories exist for each level.

Affected children will often achieve urinary continence although later than their age-adjusted normal peers (Roijen et al., 2001). Generally, daytime continence is achieved first, followed by nighttime continence within the next year. Overall, 14% (Silva et al., 2009) to 34% (Richardson and Palmer, 2009) of children are continent of urine. The median age for achieving continence in those with high intellectual capacity and diplegia or hemiplegia is 3.6 to 4.1 years. For those with low intellectual capacity and tetraplegia, this milestone is achieved much later (10.1 to 13.2 years) (Roijen et al., 2001). Most studies do not correlate mobility (or GMFCS level) with the achievement of continence (Ersoz et al., 2009; Murphy et al., 2012; Silva et al., 2009). One study of 97 children who were evaluated using a standardized dysfunction voiding symptom survey found that 1 of 4 who were able to walk had LUT dysfunction compared with 3 of 4 who were unable to do so ($P < 0.001$) (Silva et al., 2009). LUT symptoms were more prevalent as the children aged (Murphy et al., 2012; Silva et al., 2009).

The incidence of urinary symptoms in children with CP varies among studies, ranging from 16% (Murphy 2012) to 94% (Gündoğdu et al., 2013). Females are more likely than males to present with LUT symptoms (Ersoz et al., 2009; Silva et al., 2009). The most common symptom is incontinence, ranging from 23% to 94%; most noted a prevalence of 35% to 45% (Gündoğdu et al., 2013; Murphy et al., 2012; Richardson and Palmer, 2009; Roijen et al., 2001). Urgency and frequency was also reported (Murphy et al., 2012). Monosymptomatic (nighttime only) enuresis is seen in 3% (Richardson and Palmer, 2009) to 13% (Silva et al., 2009). UTI was also variable occurring in 5% to 57% (Ersoz et al., 2009; Gündoğdu et al., 2013; Silva et al., 2009, 2010). When evaluated, constipation was detected in 33% to 66% (Gündoğdu et al., 2013; Silva et al., 2009, 2010). Upper urinary tract deterioration, defined primarily as hydronephrosis, is uncommon, occurring in less than 5%, with a range of 0.5% to 12% (Gündoğdu et al., 2013; Murphy et al., 2012; Silva et al., 2009, 2010). Other parameters of deterioration include asymmetric renal size, VUR, and microlithiasis (Gündoğdu et al., 2013; Murphy et al., 2012; Silva et al., 2009). Factors raising the risk for upper urinary tract deterioration include increasing age, clinical symptoms of detrusor sphincter dyssynergia (retention, interrupted voiding, hesitancy), and recurrent UTI (Gündoğdu et al., 2013).

Pathogenesis

The etiology of urinary tract symptoms in some children with CP may be related to abnormal LUT function rather than to decreased mobility or ability to communicate.

Normal UDS are found in one-third of children with CP (Silva et al., 2009). Detrusor overactivity is noted in approximately 30% (Gündoğdu et al., 2013; Murphy et al., 2012) to 61% (Decter et al., 1987). Detrusor underactivity is documented in 6% (Murphy et al., 2012). Bladder capacity is less than expected in 42% to 93% (Ersoz et al., 2009; Gündoğdu et al., 2013; Silva et al., 2009). Detrusor sphincter dyssynergia is found in approximately 12% (Decter et al., 1987; Gündoğdu et al., 2013).

Thirteen percent may have an elevated postvoid residual urine volume (Silva et al., 2009). Uroflow patterns include a bell-shaped curve in 63%, a staccato pattern in 17%, an intermittent pattern in 13%; a plateau-shaped pattern in 3%, and a tower-shaped pattern in 3%) (Ersoz et al., 2009).

Specific Recommendations

Although many affected children may have LUT symptoms, upper urinary tract deterioration is rare. Therefore, most can be managed initially with minimal investigation and conservative management. In those with frequency, urgency, and/or incontinence, **initial investigation should include a urinalysis and culture to rule out UTI, and a minimally invasive uroflow and postvoid residual urine measurement.** Conservative measures such as timed voiding with or without antimuscarinic therapy may be instituted**. If these measures fail, further investigation with UDS may be indicated. In addition, children presenting with factors known to be associated with upper urinary tract deterioration, such as recurrent UTI or clinical symptoms of detrusor sphincter dyssynergia (urinary retention, interrupted voiding, hesitancy), warrant a more aggressive investigation including renal/bladder ultrasonography and UDS. VCUG is indicated in the presence of UTI or DSD.** In patients with severe CP (GMFCS grade IV and V), selective dorsal rhizotomy has been used to treat severe limb spasticity, but has also been shown to significantly improve bladder function in the same patients (D'Aquino et al., 2018).

Conditions of the Brain (Tumors/Infarcts/Encephalopathies)

Presentation

Children with neurogenic bladder resulting from central nervous system (CNS) tumors most commonly present with urinary incontinence and urinary retention (Nguyen et al., 2010; Soler and Borzyskowski, 1998). Other presenting symptoms include UTI, straining/difficulty voiding, hydronephrosis, and urinary urgency (Nguyen et al., 2010; Soler and Borzyskowski, 1998). In some children, development of bladder symptoms heralds progression or recurrence of the disease (Soler and Borzyskowski, 1998).

Pathogenesis

UDS of children with neurogenic bladder resulting from CNS tumors demonstrate poor compliance, inability to void, high voiding pressures, detrusor overactivity, elevated postvoid residual urine, and abnormal urinary sphincter function (Nguyen et al., 2010; Soler and Borzyskowski, 1998). There was no correlation between tumor location and any specific urodynamic parameter, nor was there a difference in urodynamic findings in patients with intracranial versus extracranial tumors or in those with suprasacral versus sacral involvement (Nguyen et al., 2010).

There is little literature related to neurogenic dysfunction that arises from other brain conditions such as encephalopathies and infarcts in children. One study noted that voided volume and rate of consciousness with voiding was significantly lower in newborns with hypoxic ischemic encephalopathy (HIE) than those without HIE (Wen et al., 2012). Those with HIE had significantly higher postvoid residual urine volumes and voiding frequency (Wen et al., 2012)

Specific Recommendations

Because various types of storage and voiding dysfunction can occur independent of tumor location, routine urologic investigation including renal ultrasonography and UDS in all children with CNS tumors is recommended (Nguyen et al., 2010; Soler and Borzyskowski, 1998). Children with encephalopathy may be at risk for bladder dysfunction and should be screened with clinical history. Those who are symptomatic warrant investigation with renal ultrasonography and UDS.

Conditions of the Spinal Cord

Traumatic Injuries

Presentation

Despite increased exposure to and the potential for traumatic SCI, **such injuries are rarely encountered in children.** The incidence in Sweden is 2.6 cases per 1 million children per year (Augutis and Levi, 2003). In the United States, the estimated incidence of hospital admission for SCI is 170 per 1 million in the population younger than 21 years of age, and the incidence of SCI is 24 per 1 million (Piatt, 2015). **The incidence tends to increase geometrically with age, and the incidence of SCI is six times greater for adolescents than for children** (Anderson and Schutt, 1980; Piatt and Imperato, 2018) (Fig. 34.18). When an injury does occur, it is more likely to happen in a male than a female child, and it is usually the result of a motor vehicle or bicycle accident (24% to 52%), a fall from a high place, a gunshot wound, or a diving or sports incident (Augutis and Levi, 2003; Brown et al., 2001; Cass et al., 1984; Cirak et al., 2004; Decter and Bauer, 1993; Hadley et al., 1988). The type of causative injuries varies with age, with infants more prone to injury from a motor vehicle accident (71%), toddlers and children injured secondary to a fall (48% and 34%, respectively) and adolescents having a sports-related event (29%) (Cirak et al., 2004). An injury may also occur iatrogenically after surgery to correct scoliosis, kyphosis, or other intraspinal processes or congenital aortic anomalies or after ligation of a patent ductus arteriosus (Batista et al., 1995; Cass et al., 1984). Neonates are particularly prone to a hyperextension injury during a high forceps delivery (Adams et al., 1988; Lanska et al., 1990). Among younger children, girls are affected as often as boys (Ruge et al., 1988).

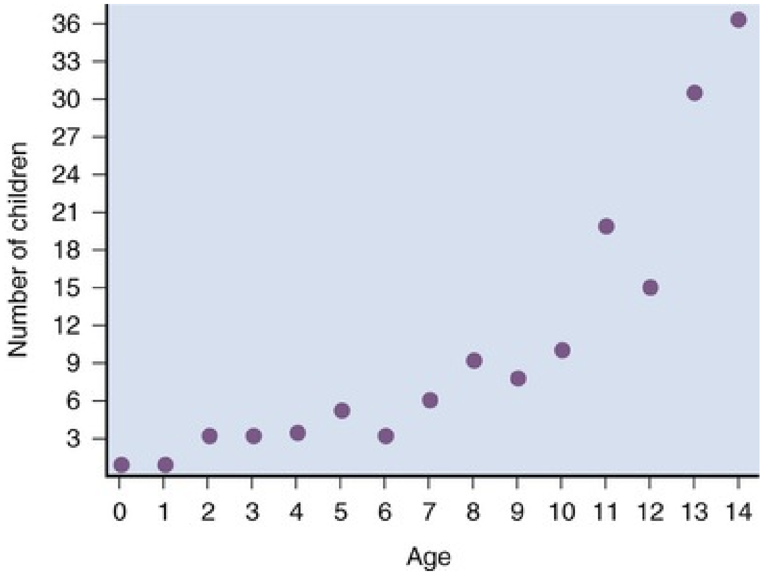

FIG. 34.18 Increasing frequency of spinal injury with age. (From Anderson JM, Schutt AH. Spinal injury in children: a review of 156 cases seen from 1950 through 1978. *Mayo Clin Proc* 55(8):499–504, 1980.)

Pathogenesis

SCIs in children are intrinsically different from those in adults because of a variety of factors, including the mechanism of injury and the difference in configuration of the brainstem and spinal cord in children compared with adults. In addition, the horizontal versus vertical orientation of the facet joints in vertebral bodies that predisposes to anteroposterior subluxation in children, the delayed supportive effect of the paraspinous musculature and ligaments, and the relative heaviness of the head, which causes a fulcrum of maximal flexion of the upper cervical region in infants and young children, all contribute to a high degree of hypermobility that places the child's spinal cord at risk for ischemic necrosis (Decter and Bauer, 1993).

Specific Recommendations

The LUT dysfunction that ensues is not likely to be an isolated event but is usually associated with loss of sensation and paralysis of the lower limbs. Radiologic investigation of the spine may not reveal any bony abnormality, although momentary subluxation of osseous structures resulting from the elasticity of the vertebral ligaments can result in a neurologic injury (Pollack et al., 1988). This condition has been seen only in children (usually younger than 8 years of age) and has been labeled **S**pinal **C**ord **I**njury **W**ith**O**ut **R**adiologic

Abnormality (SCIWORA) (Pang and Pollack, 1989; Pang and Wilberger, 1982). Overall, SCIWORA can account for up to 38% of SCIs in children (Brown et al., 2001). Myelography and CT show swelling of the cord below the level of the lesion (Adams et al., 1988; Lanska et al., 1990). **Often, what appears to be a permanent lesion initially turns out to be a transient phenomenon with time.** Although sensation and motor function in the lower extremities may be restored relatively quickly, the dysfunction involving the LUT and rectum may persist considerably longer.

During the acute phase of the injury, the bladder is often acontractile and the urethral sphincter nonreactive, although normal-appearing bioelectric potentials can be recorded on sphincter EMG (spinal shock). Over a variable period, detrusor contractility and sphincter reactivity return as spinal cord edema subsides. With this return of function, an **overactive detrusor and bladder-sphincter dyssynergy develop if the lateral reticulospinal cord pathways to and from the brainstem have been disrupted. When the lesion affects the cauda equina, there is probably little to no return of bladder or urethral sphincter function.** Sacral sensation and peripheral reflexes are not good indicators of ultimate LUT function (Shenot et al., 1998). Over time, the predominant urodynamic pattern in patients with a thoracic-level lesion is an overactive detrusor with DSD, high voiding pressures, eventual hydronephrosis, and VUR. Often children exhibit a highly compliant bladder for a portion of bladder filling but then have C-fiber–mediated, small, ineffective rhythmic contractions of the detrusor with simultaneous waxing and waning of external urethral sphincter activity. Some urinary leakage may occur with these contractions, but in general the bladder does not empty with them. **Patients with an upper thoracic (above T6) or cervical lesion are likely to exhibit autonomic dysreflexia with a spontaneous discharge of α_1-stimulants during bladder filling and with contractions of the detrusor. Monitoring blood pressure and availability of α-antagonists are mandatory during VCUG or UDS** (Perkash, 1997; Vaidyananthan et al., 1998b).

If urinary retention occurs immediately after the injury, an indwelling Foley catheter is passed into the bladder and left in place for as short a time as possible until the patient's condition is stable and aseptic intermittent catheterization can be started safely on a regular basis (Barkin et al., 1983; Guttmann and Frankel, 1966). There is no difference in the incidence of urinary infection or in the development of stones in patients using sterile versus clean catheterization techniques to empty the bladder (Prieto-Fingerhut et al., 1997;

Van Hala et al., 1997). Rates of infection range as high as 60% to 80% (Biering-Sørensen et al., 1999), and stone formation occurs in 1.5% to 3% within the first 5 years after the trauma (Donnellan and Bolton, 1999; McKinley et al., 1999). When the child starts to void again, the timing of catheterization can be regulated so that it is used as a means of measuring the residual urine after a spontaneous void. Residual urine volumes of 25 mL or less are considered safe enough to allow reducing the frequency or even stopping the catheterization program (Barkin et al., 1983). If there is no improvement in LUT function after 4 to 6 weeks, UDS are conducted to determine whether the condition is the result of spinal shock or an actual nerve root or SCI. An acontractile detrusor is not uncommon under these circumstances (Iwatsubo et al., 1985). On the other hand, EMG recording of the sphincter often reveals normal motor units without fibrillation potentials but absent sacral reflexes and a nonrelaxing sphincter with bladder filling, a sign that transient spinal shock has occurred (Iwatsubo et al., 1985). The outcome of this situation is guarded but good, because most cases resolve completely as edema of the cord in response to the injury subsides, leaving no permanent damage (Fanciullacci et al., 1988; Iwatsubo et al., 1985).

Incomplete emptying may be enhanced by the judicious use of α-sympatholytic agents (Al-Ali et al., 1999). **The goal is balanced voiding at pressures lower than 40 cm H_2O,** which reduces the 30% risk for urinary tract deterioration seen in poorly managed patients (Giannantoni et al., 1998; Kim et al., 1998). If this cannot be achieved, then CIC is continued. Antimuscarinics, either orally or intravesically (Vaidyananthan et al., 1998a; Wein, 1998), or capsaicin (an inhibitor of C-fiber stimulation (Wiart et al., 1998) have been added and are effective in reducing an overactive detrusor, but at the cost of significant side effects. Alternative treatments that have been effective to ensure complete emptying at low pressure include external urethral sphincterotomy (Kim et al., 1998), urethral stent placement (Chancellor et al., 1999), or injection of BTA into the external sphincter (Kuo, 2003; Schurch et al., 1997). In some cases, a continent catheterizable abdominal urinary stoma may be created to facilitate self-catheterization in patients with low cervical or upper thoracic lesions who cannot easily catheterize themselves (Sylora et al., 1997).

Most permanent traumatic injuries involve either the upper thoracic or the cervical spinal cord but some affect the cauda equina region. The sacral cord injury most likely produces a lower motor neuron deficit of the striated urethral sphincter that usually leads to low pressure bladder emptying with little risk for upper urinary tract deterioration. However, it probably necessitates medical and/or surgical management to achieve continence. On the other hand, upper SCIs produce an upper motor neuron lesion with an overactive detrusor and DSD. The potential danger from this outflow obstruction is obvious (Donnelly et al., 1972). Substantial residual urine volumes, high-pressure reflux, urinary infections, and their sequelae are the leading causes of long-term morbidity and mortality in patients with SCI (Giannantoni et al., 1998). Even patients who voluntarily urinate and are continent or who involuntarily but spontaneously void to completion are not immune to urinary tract changes (Decter and Bauer, 1993). **UDS are imperative to identify which patients are at risk** (Barkin et al., 1983)**. These studies should be performed within 2 to 3 months after the injury, again 6 to 9 months later, and possibly at 2 years after the trauma** to determine the stability of LUT function, the need for continued CIC, and whether adjuvant drug or surgical therapy should be added (or continued) to achieve good long-term success. When these measures are employed judiciously, effective management can be achieved (Pannek et al., 1997). **Renal ultrasonography early in the course and, if video UDS are not available, a VCUG if signs of bladder outlet obstruction are present or if recurrent urinary infection ensues are also recommended. Investigation for VUR is indicated if the patient has repeated febrile UTI or develops hydronephrosis** (Phillips et al., 1997)**. Because stone formation can be insidious, periodic ultrasonographic imaging of the kidneys and bladder is necessary**. Early identification and proper management may prevent the signs and effects of bladder outlet obstruction before they become apparent on radiographic examination of the urinary tract (Ogawa et al., 1988; Pearman, 1976).

Tranverse Myelitis

Presentation

Transverse myelitis is a clinical syndrome caused by an immune-mediated inflammatory process that affects the spinal cord (DaJusta et al., 2008). Approximately 1400 new cases are diagnosed in the United States annually, and 28% of affected individuals are children (Krishnan et al., 2004). The incidence peaks between 10 and 19 years of age and again in the third decade of life (Krishnan et al., 2004). Males and females have an equal incidence (DaJusta et al., 2008). The diagnosis is made by accepted criteria, including sensory, motor, or autonomic dysfunction attributable to the spinal cord, bilateral neurologic signs and/or symptoms, a clearly defined sensory level, and inflammation in the spinal cord as demonstrated by cerebrospinal fluid pleocytosis or an increased T2 signal on MRI (Fig. 34.19) (Krishnan et al., 2004).

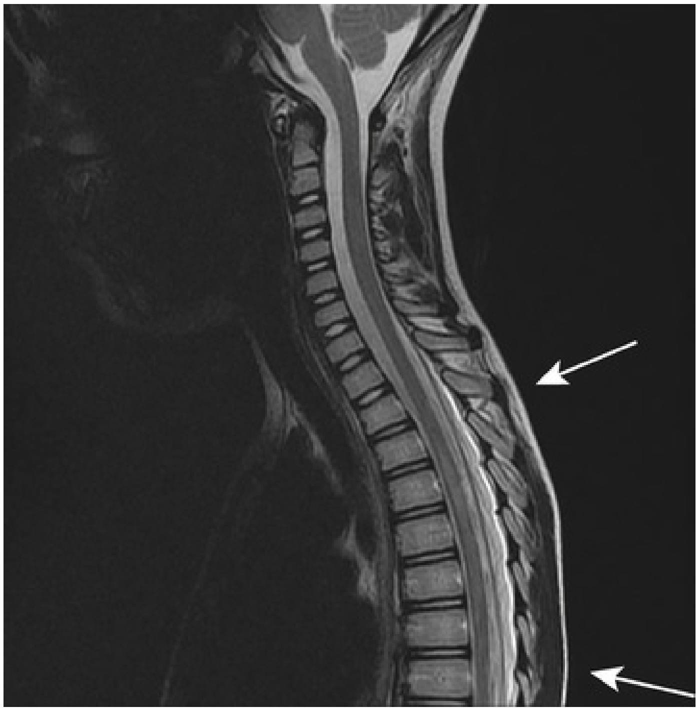

FIG. 34.19 T2-weighted sagittal MRI scan of the spine of an 8-year-old boy who presented with lower extremity weakness and urinary retention. Increased signal intensity of the spinal cord is noted from T3 to T8 *(arrows).*

Transverse myelitis usually presents with sudden lower back pain or lower extremity muscle weakness that rapidly progresses to paralysis and often to urinary retention (Knebusch et al., 1998). Bladder dysfunction may present simultaneously with the motor dysfunction or more commonly follows it (DaJusta et al., 2008). Bowel dysfunction is also likely to occur at presentation (DaJusta et al., 2008). In the acute stage of transverse myelitis, there may be a varying period of spinal shock that may persist for up to 6 weeks (Guttmann, 1970) and which gradually progresses to spasticity if total resolution does not occur. The segment of the spinal cord affected by the disease determines the motor deficit (DaJusta et al., 2008). During the acute phase of the disease, treatment options include steroids, plasma exchange, and intravenous IgG (DaJusta et al., 2008). Recovery from the disease usually commences within 2 weeks to 3 months after the onset of symptoms. The most substantial recovery occurs within the first 6 months (DaJusta et al., 2008), but sometimes improvement continues up to 2 years postevent (Krishnan et al., 2004).

Pathogenesis

It is well documented that the most common urinary symptom in children with transverse myelitis is **urinary retention;** in fact, more than 95% of affected children will have urinary retention during the acute phase of the disease (DaJusta et al., 2008; Gatti et al., 2001; Kalita et al., 2002). **The most common urodynamic finding in the acute phase is areflexia or detrusor underactivity, found in close to 70%** (Kalita et al., 2002). Detrusor overactivity is noted in the acute phase in approximately 13%; 30% have decreased compliance, and 20% may have detrusor sphincter dyssynergia (Kalita et al., 2002). **After resolution of spinal shock, the urodynamic patterns identifiable are detrusor overactivity (59% to 90%), decreased compliance (47%), DSD (17% to 80%), and detrusor leak point pressure greater than 40 cm H_2O (12% to 33%). Detrusor underactivity is noted rarely after resolution of the acute phase of the disease** (Ganesan and Borzyskowski, 2001; Kalita et al., 2002; Tanaka et al., 2006).

Approximately one-third of children will be able to void spontaneously after the acute phase (DaJusta et al., 2008; Tanaka et al., 2006). Some children (57% to 73%) will require CIC to empty their bladder (DaJusta et al., 2008; Tanaka et al., 2006). Antimuscarinic medications are needed to manage symptoms of detrusor overactivity in 14% to 64% (DaJusta et al., 2008; Ganesan and Borzyskowski, 2001; Tanaka et al., 2006). For children whose incontinence is not resolved with CIC and antimuscarinics because of small capacity/poor compliance or unremitting overactivity, injection of BTA and bladder augmentation has been helpful (Tanaka et al., 2006). Up to 77% may have persistent bowel dysfunction; consequently, most require active bowel management (Tanaka et al., 2006).

Although some reports have not correlated LUT function with recovery of motor function (Ganesan and Borzyskowski, 2001; Tanaka et al., 2006), other larger studies have demonstrated an association (DaJusta et al., 2008; Dunne et al., 1986; Kalita et al., 2002). One study found that children with full motor recovery were likely to also have full recovery of LUT symptoms, that is, normal voiding with continence and no requirement for antimuscarinic medication. It was also noted that partial recovery of motor function was associated with partial recovery of LUT function, meaning that children could void spontaneously but required antimuscarinics for incontinence. Children with no motor recovery or those who were wheelchair dependent were likely to require CIC and possibly antimuscarinics (DaJusta et al., 2008).

Profound urologic complications have been noted infrequently in children with transverse myelitis including UTI (DaJusta et al., 2008), VUR, hydroureteronephrosis, chronic renal insufficiency, and bladder calculi and diverticula (Kalita et al., 2002). One study documented an association between late initiation of CIC and increased risk for decreased bladder compliance and upper urinary tract deterioration. In this series, upper urinary tract deterioration, where hydronephrosis or VUR was noted, occurred in 5% of children. In this series, neither neurologic examination nor urinary symptoms were able to predict the risk for upper urinary tract deterioration. In addition, ambulatory status did not correlate with urodynamic findings (Tanaka et al., 2006).

Specific Recommendations

UDS and a baseline renal/bladder ultrasound examination, once the acute phase of the neurologic injury has stabilized, are suggested to identify those patients who may have DSD. Children with bladder underactivity and/or DSD will benefit from the early introduction of CIC and antimuscarinic therapy, respectively (Tanaka et al., 2006). UDS should be performed again after resolution of the acute phase (at approximately 6 months) to guide therapy for incontinence and preservation of the upper urinary tract. Voiding or radionuclide cystography is indicated in the presence of DSD or febrile UTIs if video UDS are not available. As these children are at risk for upper urinary tract deterioration, annual follow-up evaluation including renal ultrasonography is recommended as outlined in Table 34.3. UDS are advisable if there is a change in LUT symptoms or in ultrasound images.

Key Points: Conditions of the Pelvis, Central Nervous System Insults, and Conditions of the Spinal Cord

- Spinal cord abnormalities including tethered spinal cord, thickened or fatty filum terminale, and lipoma occur in 18% to 50% of patients with an anorectal malformation.
- The incidence of LUTS in children with CP is 16% to 94%, and the most common symptom is urinary incontinence.

- In patients with SCI, there is an acute phase of spinal shock wherein the bladder is often acontractile and the urethral sphincter nonreactive; with resolution of spinal shock, an overactive detrusor and bladder-sphincter dyssynergy most commonly develop.
- Patients with a cervical or thoracic spine lesion above T6 are likely to exhibit autonomic dysreflexia during bladder filling and detrusor contractions.

Functional Disorders of the Lower Urinary Tract in Children

Paul F. Austin MD, Abhishek Seth MD

Clinical Significance

Functional disorders of the lower urinary tract (LUT) encompass abnormalities in the filling and/or emptying phases of the bladder and include a broad spectrum of clinical entities that vary in their cause and prognosis. These are functional disorders in children that do not have a readily identifiable neurologic or anatomic abnormality. These LUT disorders are thought to originate from behavioral factors that affect toilet training and inhibit the development of normal urinary control. *Lower urinary tract dysfunction (LUTD), bladder and bowel dysfunction*, and the antiquated *dysfunctional elimination syndrome* are terms that describe the common array of symptoms that include overactive bladder (OAB), voiding postponement, underactive bladder, dysfunctional voiding, primary bladder neck dysfunction, giggle incontinence, vaginal reflux, pollakiuria, and enuresis.

Evidence-based medicine lends support to the hypothesis that LUTD can predispose children to recurrent urinary tract infections (UTIs) and vesicoureteral reflux (VUR), with a potential for significant impact on subsequent LUT and renal function. Beyond these largely urologic sequelae, however, the impact of symptoms such as daytime incontinence are profound and can affect the behavioral, emotional, and social aspects of a child's daily life. Timely diagnosis and a coherent therapeutic approach are therefore paramount in the successful treatment of these physically and emotionally distressing disorders.

Epidemiology

LUTD is commonly encountered in daily practice, accounting for up to 40% of pediatric urology clinic visits annually (Feldman and Bauer, 2006). Cross-sectional studies confirm that functional LUT problems are prevalent, with 22% of school-age children reporting at least one LUT symptom. The most common urinary symptoms cited included holding maneuvers (19.1%) and urgency (13.7%) (Vaz et al., 2012).

United States

Daytime incontinence is estimated to affect up to 7 million children in the United States 6 years of age or older (Franco, 2012). To date, studies have focused primarily on daytime versus nighttime incontinence and have not attempted to differentiate the type of daytime incontinence. OAB, characterized by urgency, is the most commonly encountered LUT disorder in children and appears to have a peak incidence between 5 and 7 years of age, although its true prevalence is difficult to determine (Franco, 2007). Chandra (1998) reported the responses to 583 questionnaires completed by families of children between 5 and 9 years of age and found that urinary urgency and pelvic tightening maneuvers to postpone voiding and prevent incontinence were the voiding issues most frequently reported. Urge incontinence was present in 7% of girls and 3% of boys.

International

A study by Hellström et al. (1990) of 7-year-old Swedish children entering school revealed that 21% of girls and 18% of boys had moderate-to-severe urinary urgency. Daytime urinary incontinence occurred once weekly in 3.1% of girls and 2.1% of boys. A Japanese study of 6917 school-age children demonstrated an overall prevalence rate of 17.8% for OAB (Kajiwara et al., 2006). Interestingly, this epidemiologic survey found a nearly equal prevalence of OAB between boys and girls of 19.1% and 16.6%, respectively. An Australian study addressed the frequency of voiding disorders in school-age children (Sureshkumar et al., 2009). This study of 2856 students reported that 19.2% of children had experienced at least one episode of daytime incontinence in the previous 6 months, with 16.5% having experienced more than one wetting episode and only 0.7% experiencing wetting on a daily basis. Independent risk factors for daytime incontinence included nocturnal enuresis, female sex, history of UTI, and encopresis (Sureshkumar et al., 2009).

A large cross-sectional study of more than 19,000 children between 5 and 13 years of age was performed in the Republic of Korea and evaluated the prevalence of OAB by parental questionnaire (Chung et al., 2009). The overall prevalence of OAB was 16.6% and decreased with age from 23% to 12% by 13 years of age (Chung et al., 2009). Compared with other children, those with OAB had a greater prevalence of nocturnal enuresis, constipation, fecal incontinence, UTI, delayed bladder control, and poor toilet facilities.

Gender and Age-Related Demographics

Robson (1997) found that **daytime incontinence varies with both age and gender.** This group reported that the prevalence of daytime wetting at least once every 2 weeks was 10% from 5 to 6 years of age, 5% from 6 to 12 years of age, and 4% from 12 to 18 years of age. In a population survey of 1192 individuals 1.5 to 27 years of age, daytime incontinence occurred in 13% of children 4 years of age, 7% of children 5 years of age, 10% of children 6 years of age, and 5% of children 7 years of age (Bloom et al., 1993). **Studies on the prevalence of voiding disorders in school-age children indicate that daytime urinary incontinence is two to five times more common in girls** (Sureshkumar et al., 2009). Girls also tend to have a lower incidence of frequency, more incontinence, and a larger percent expected bladder capacity (EBC) than boys (Van Batavia et al., 2017). Hellström et al. (1990) found that daytime incontinence was more common in girls (6.7%) than in boys (3.8%) and that most children with incontinence had other lower urinary tract symptoms (LUTS). A retrospective analysis by Arlen et al. identified an association between body mass index (BMI) and LUT or bowel-bladder dysfunction (BBD) in school-age children. Furthermore, children with a BMI greater than the 85th percentile were more likely to experience treatment failure (Arlen et al., 2017).

Self-Esteem and Quality-of-Life Issues

Multiple epidemiologic and cross-sectional studies demonstrate that between 5% and 20% of children suffer with daytime incontinence (Hellström et al., 1990; Kajiwara et al., 2004; Joinson et al., 2006; Sureshkumar et al., 2009). The reported incidence of incontinence ranges from 1.2% daily to 3.6% at least twice per week (Hellström et al., 1990). Remarkably, the majority of parents surveyed did not seek medical attention for their child's incontinence, and teachers recognized only 3% of the children in their classroom who actually suffered from daytime wetting (Sureshkumar et al., 2009). These statistics would make it appear that LUTD and its sequelae are of nominal consequence in the daily lives of young children. Various studies examining the impact of symptoms like urinary incontinence on self-esteem and quality of life (QoL) in children would suggest otherwise. In a literature review analysis, Collis et al. found that a majority of pediatric studies demonstrated a reduced QoL in children with nocturnal enuresis, bladder dysfunction, bowel dysfunction, and combined BBD (Collis et al., 2019). Furthermore, they found that parents' QoL and socioemotional functioning were also negatively affected.

Given the emerging recognition of patient perspectives in health care over the past decade, QoL assessment is an important part of incontinence research. Measurement of QoL in children with urinary incontinence gives a child-centric estimate of the impact that incontinence makes in daily life. In a survey of 1185 children, both in the United States and Australia, school-age children were asked to grade the severity of 20 different stressful life events (Ollendick et al., 1989). Of the different situations examined, "wetting pants in class" was rated as the third most stressful, which underscores the importance of urinary control in school-age children and their peers. Additionally, attention has been raised with associated school bullying and pediatric LUTS (Ching et al., 2015).

Thibodeau et al. (2013) prospectively studied 40 children (10 males and 30 females), between 5 and 11 years of age with non-neurogenic daytime wetting. The Dysfunctional Voiding Symptom Score (DVSS), originally put forth by Farhat et al., (2000) was used to quantify the severity of LUTS and was completed by both parents and children. Parents and their children also completed the Pediatric Urinary Incontinence Quality of Life Score tool (Pin-Q), originally developed by Bower et al. (2006), which measures the emotional impact that urinary incontinence has on a child. There was no statistically significant difference between parent and child scores for symptoms (DVSS) and quality of life (Pin-Q), supporting the parent's awareness and accurate perception of the child's symptoms and the shared impact on their QoL. DVSS and Pin-Q responses were positively correlated (i.e., as DVSS scores increased, the Pin-Q showed a corresponding rise). Similarly, Noordhoff et al. examined the efficacy of The Dutch Vancouver Symptom Score for Dysfunctional Elimination Syndrome (VSSDES) and the PinQ in assessing QoL in 64 children who had received urotherapy. The PinQ questionnaire was able to detect clinically important changes over time, suggesting that symptoms had improved with extended urotherapy. In contrast, the VSSDES was not useful in detecting clinically important changes, over time, in response to therapy (Noordhoff et al., 2018). This study demonstrates the heterogeneity existing in questionnaires and psychometric testing used in the diagnosis and management of bladder and bowel dysfunction, which was summarized by Jiang et al., thus validating the need for standardization (Jiang et al., 2018).

Comorbidities

Urinary Tract Infections

A clear and consistent relationship has been repeatedly demonstrated in multiple studies between LUTD and UTIs (Yang et al., 2018). Bauer (2002) suggested that UTIs are not only an effect of dysfunctional voiding but also may precipitate the development of LUTD, specifically OAB.

Hellström et al. (1990) disseminated a questionnaire to analyze the micturition habits and UTI history of more than 3500 school-age children. Girls with daytime wetting, urgency, and emptying difficulties had a higher prevalence of UTI history than those without symptoms. Hoebeke et al. (2001a) prospectively studied 1000 children during a 4-year study period with video-urodynamics to ascertain the cause and epidemiology of LUTD. The incidence of UTI was significantly higher in girls than in boys. In addition, boys with LUTD had no greater risk for UTI. In girls with underactive bladder, there was a significantly higher incidence of UTI.

Chen et al. (2004) performed a multivariate analysis on 2759 children to elucidate the relationships among LUTD, UTI, and VUR. Their data demonstrated a higher rate of LUTD in girls (43.7%) than in boys (23.8%), with 44% of children who had a history of UTIs also having concomitant LUTD. Interestingly, they observed no association of UTI or VUR individually, but rather found that LUTD was noted only when both UTI and VUR were present.

In a recent retrospective review, Van Batavia et al. (2013) determined how many children who initially presented with LUTD had a history of UTIs. Of 623 children diagnosed with LUTD, one-third had a history of UTIs, with the prevalence rate being significantly higher in girls than in boys. When stratified by specific LUT conditions, girls with underactive bladder and dysfunctional voiding had the highest UTI rates. Not surprisingly, **the association between UTIs and LUTD was most often noted for LUT conditions in which urinary stasis occurs.**

Vesicoureteral Reflux

There is a known association between LUTD and VUR, and VUR may be secondary to the LUT condition. Lapides and Diokono (1970) **first described**

the association between dysfunctional voiding and VUR. Since that time, a number of authors have expanded on the description and nature of the association. In the late 1970s, **Koff et al.** (1979) **demonstrated that voiding against a closed sphincter can increase bladder pressure and may contribute to the development and persistence of VUR. The incomplete bladder emptying that occurs in children with LUTD can lead to urinary stasis with subsequent UTI causing inflammatory changes in the bladder wall that stimulate hypertrophy and overactivity. This is particularly true in older children who manifest with febrile UTIs after toilet training has been completed. It has been theorized that detrusor hypertrophy can alter the closure mechanism at the ureterovesical junction, leading to reflux** (Yeung et al., 1998)**. Gaither et al.** (2018) **provided further evidence that dilating reflux and female sex were risk factors for development of LUTD; however, BMI and prophylactic antibiotics were not significant risk factors**.

One of the first studies to systematically address the relationship between LUTD and VUR was performed by Van Gool et al. (1992), who distributed a questionnaire to all children enrolled in the European arm of the International Reflux Study in Children. Extrapolating from the questionnaire results, the prevalence of dysfunctional voiding was approximately 18%. **A strong association was observed between recurrent UTI and LUTD, and in those children with spontaneous resolution of their reflux, the prevalence of LUTD was much lower.**

Koff et al. (1998) reported their experience on 143 children with primary VUR who either resolved spontaneously or were surgically treated. LUTD was present in 66 (43% of the cohort), with 54 (82%) of these children having a breakthrough UTI and undergoing reimplantation compared with only 18% without LUTD. Of 70 children who had a breakthrough UTI, LUTD was present in 54 children (77%); in 73 patients who did not have a breakthrough infection, LUTD was present in only 12 (16%) children. Additionally, if VUR resolution did occur, the time for resolution lagged by 1.6 years in those with LUTD compared with those without LUTD. Finally, **unsuccessful surgical outcomes involving persistent, recurrent, and contralateral reflux occurred only in children with BBD.**

The association between LUTD and treatment failure after surgical correction for reflux has been borne out in a number of clinical studies. Regardless of surgical treatment modality (i.e., endoscopic vs. open reimplantation), ongoing LUTD has been shown to be associated with a higher failure rate (Peters et al., 2010; Tekgül et al., 2012). Capozza et al. (2002) treated a total of 320 children between 3 and 11 years of age with subureteral injection for grades II to IV VUR. They found untreated LUTD to be highly associated with endoscopic treatment failure at 6-month follow-up.

Targeted treatment for LUTD has been demonstrated to improve spontaneous resolution rates for VUR (Fast et al., 2013; Willemsen and Nijman, 2000). In a recent study by Fast et al. (2013), patients diagnosed and treated for LUTD who had concomitant VUR at or near the time of diagnosis underwent targeted treatment for their specific dysfunction along with antibiotic prophylaxis. VUR was monitored with serial voiding cystourethrogram or video-urodynamics. After a mean of 3.1 years of treatment, VUR resolved with targeted therapy in 26 of 58 ureters. All of these patients had a history of UTIs before starting targeted intervention. Interestingly, they found that resolution rates for VUR were similar regardless of VUR grade. Resolution or significant improvement of reflux was greater in patients with dysfunctional voiding (70%) compared with those who had OAB (38%) or underactive bladder (40%). The outcomes of children with and without BBD was compared in two longitudinal studies (Randomized Intervention of Children with Vesicoureteral Reflux and Careful Urinary Tract Infection Evaluation), concluding that patients with combined BBD and VUR are at higher risk for developing recurrent UTIs than children with BBD or VUR alone (Shaikh et al., 2016).

Psychological Associations

Recently, there has been an emerging awareness of the strong association that exists between neuropsychiatric comorbidities and LUTD in children. In fact, **functional causes of LUTD are believed by many to originate from behavioral issues that evolve from personal stressors and/or adverse events that occurred around the time of toilet training** (Feldman and Bauer, 2006)**. A study of nonbiologic determinants of BBD performed by Martins et al. reported that more severe symptoms were observed in urology outpatient clinics when the children were from an unplanned pregnancy, attended daycare, or had school problems. This suggests that environmental factors, including personal and familial interactions, had an important effect on continence of school-age children** (Martins et al., 2016).

Between 20% and 40% of children with daytime urinary incontinence are affected by comorbid behavioral disorders (Joinson et al., 2006; von Gontard et al., 1998b). Additionally, a number of epidemiologic studies have reported clinically significant behavioral problems in up to one-third of children with enuresis (Hirasing et al., 1997; Liu et al., 2000). This is two to four times higher than in children without enuresis and is comparable with rates of psychosocial problems in other pediatric chronic illness groups. Other studies have investigated the psychological problems associated with specific syndromes responsible for daytime urinary incontinence. These investigators found a higher rate of behavioral problems in children with voiding postponement compared with those who had urge incontinence as their major complaint (Lettgen et al., 2002; von Gontard et al., 2011). Moreover, some have suggested that voluntary holding with postponement of voiding is acquired and may be reflective of ongoing behavioral issues (von Gontard et al., 1999). Using a Child Behavior Checklist (CBCL), Marciano et al. (2018) evaluated the prevalence of internalizing and externalizing behavioral problems in children with LUTD. Having enuresis in addition to LUTD was associated with higher frequency of externalizing problems including aggressive behaviors. The presence of a behavioral problem was further associated with a poorer QoL.

Oliver et al. (2013) explored the prevalence of psychosocial comorbidities and their relationship to children presenting with LUTD. Data were prospectively collected on patients 6 to 17 years of age. Parents completed a 21-question LUTS score based on a validated questionnaire and a psychosocial questionnaire that screened for stressful life events and psychological diagnoses. Of the 358 patients examined, 32% had a recent life stressor and 23% had a comorbid psychiatric disorder. Younger age correlated with a higher LUTS score. Children with a recent life stressor, psychiatric disorder, or the two comorbidities had a significantly higher LUTS score than children without comorbidities. This study lends support to the recommendation for screening of psychosocial comorbidities during the evaluation of pediatric LUTD.

In perhaps one of the largest epidemiologic studies to look at the association between daytime urinary incontinence and neuropsychiatric issues in children, researchers found a significantly increased rate of psychological problems among children who wet themselves compared with those who were dry (Joinson et al., 2006). Of the over 8000 children between 7.5 and 9 years of age who were studied, those with daytime wetting had significantly increased rates of attention deficit/hyperactivity disorder (ADHD) (24.8%), conduct disorders (11.8%), separation anxiety (11.4%), and oppositional behavior (10.9%). The increased vulnerability to psychological problems in children with daytime urinary incontinence underscores the importance of parents seeking early intervention for the condition to help prevent later psychological problems. Comorbidity of ADHD with nocturnal enuresis and daytime urinary incontinence has been shown to arise from nongenetic factors and are likely caused by etiologic and pathogenetic links (von Gontard and Equit, 2015). Moreover**, clinicians should be cognizant of the association with disorders such as ADHD in children with daytime wetting, because this is likely to interfere with treatment success.** In addition to an association with more severe nocturnal enuresis, Kovacevic et al. (2018) found that patients with ADHD were significantly more responsive to medication for nocturnal enuresis compared with behavior modification, suggesting that early intervention by pharmacologic treatment is beneficial for children with ADHD.

Bowel Dysfunction

It has long been recognized that an intimate association exists between both hindgut and LUT function. Indeed, LUTS are seen in approximately 30% of children who present with constipation (Belman, 1998). Previous reports have indicated a significant overlap in these conditions in the primary care setting, with nearly one-fourth of children with functional fecal retention also reporting daytime urinary incontinence (Loening-Baucke, 2004). As one would expect, the prevalence of these comorbid conditions is even higher at tertiary care centers. Burgers et al. (2013a) recently reported that nearly one-half of patients seen at their pediatric urology clinic for LUTS also met criteria for functional constipation.

The relationship between abnormal bowel and bladder activity is termed *bowel-bladder dysfunction (BBD)* and is part of an entity originally described by Koff et al. (1998) **as *the dysfunctional elimination syndrome*.** The International Children's Continence Society discourages using the term *dysfunctional elimination syndrome* as this connotes a particular abnormality or condition (Austin et al., 2014). *BBD* is a more descriptive comprehensive term that does not necessarily explain pathogenesis but rather encompasses this parallel dysfunction. In any event, Koff recognized the significance of bowel dysfunction; if present, its clear identification and management were paramount if treatment of the LUT condition was to be successful. Koff et al. (1998) recommended that each LUT condition be treated specifically while addressing any concomitant bowel dysfunction, often before treatment of the LUT condition.

Although an exact pathophysiologic basis for BBD has not been clearly elucidated, a number of different theories have been put forth. One theory espouses that rectal distention from fecal retention puts direct pressure on the posterior bladder wall and that this constant force in turn leads to detrusor instability, which can precipitate bladder overactivity and impair efficient bladder emptying (Lucanto et al., 2000). A second theory assumes that both the urethral and anal sphincters share a common neural input. With chronic contraction of the anal sphincter from rectal stool impaction, the pelvic floor musculature similarly contracts inappropriately, leading to secondary detrusor–external urinary sphincter dyssynergia. This vicious cycle of discoordination is what is thought to induce bladder overactivity, urinary incontinence, recurrent UTIs, and VUR (O'Regan et al., 1985).

In a recent study by Burgers et al. (2013a), researchers assessed the prevalence of functional defecation disorders in children referred to a tertiary pediatric urology outpatient clinic for LUTS. They analyzed the records of 113 patients between 4 and 17 years of age who presented with LUTS. Rome III criteria for functional constipation and functional nonretentive fecal incontinence were fulfilled by 47% and 11% of patients with LUTS, respectively. Not surprisingly, children with dysfunctional voiding were more likely to fulfill the criteria for functional constipation, and children with urge incontinence more often fulfilled the criteria for nonretentive fecal incontinence. This last point is intriguing in that it supports the notion that children with fecal incontinence and urge urinary incontinence often will not respond to a standard bowel program, which could potentially exacerbate the situation. Perhaps these children would be better served by a centrally acting agent to aid in suppression of overactivity or lack of inhibition. Clearly, there continues to be a void in our understanding of the bowel and bladder interaction in higher cortical centers and the spinal cord.

In a similar study by Combs et al. (2013), researchers sought to better illuminate the relationship between LUT and bowel dysfunction by studying 368 consecutive children who presented with LUTD. In a secondary analysis, they also sought to determine if constipation and encopresis, which are often presumed to coexist, also coexisted for their specific cohort. Overall, children with dysfunctional voiding had the highest incidence of bowel dysfunction, with constipation alone being the most frequently observed form. Somewhat surprisingly, nearly 50% of patients reporting encopresis did not have associated constipation. The majority of patients with encopresis with or without associated constipation had idiopathic detrusor overactivity, and those with the worst urgency were the ones reporting encopresis. Interestingly, in children with encopresis, severe urgency was commonly reported and after initiation of anticholinergic therapy the encopresis frequently resolved, even before the urgency had fully subsided. This finding is similar to the results of Burgers et al. (2013a), and perhaps may be secondary to an overactivity of the detrusor and the rectal wall musculature, or a lack of inhibition of detrusor and rectal muscular activity. Whether this is a centrally mediated phenomenon is unclear.

Key Points: Epidemiology, Self-Esteem and Quality-of-Life Issues, and Comorbidities

- LUTD is commonly encountered in daily practice.
- Daytime incontinence varies with both age and gender in school-age children and seems to be more common in girls.
- There is a clear and consistent relationship between LUTD and UTI, especially when urinary stasis occurs.
- There is a known association between LUTD and VUR. Continued LUTD is a risk factor for treatment failure after surgical correction for reflux. Targeted treatment for LUTD has been demonstrated to improve spontaneous resolution rates for VUR.
- Clinicians should be aware of the association between neuropsychiatric disorders and LUTD. Failure to adequately address these comorbidities is likely to interfere with treatment success.
- The relationship between abnormal bowel and bladder activity is termed *bowel-bladder dysfunction (BBD)*, and, if present, clear identification and management of any concomitant bowel dysfunction is paramount if treatment of the LUT condition is to be successful.

Terminology

The International Children's Continence Society (ICCS) is a global, multidisciplinary organization of clinicians involved in the care of children with LUTD (Austin et al., 2014). Perhaps one of the most significant impacts of the ICCS on the pediatric LUT function community was its initial terminology document (Nevéus et al., 2006). Before the publication of this document, the nomenclature used in LUTD had been endemic with transposable terms that in some cases were not completely accurate and were often confusing. Moreover, this fostered uncertainty and made it rather difficult to compare research and study outcomes among different groups. The standardization of the nomenclature for pediatric and adolescent LUT function is thus critical in providing a platform for optimal comprehension and more effective interaction and treatment among multiple health care providers who care for these patients. The ICCS revised the original terminology document to provide a current and consensus update reflecting refinement and current advancement of knowledge on pediatric and adolescent LUT function (Austin et al., 2014).

The terminology used for LUTS focuses on descriptive (as opposed to quantitative) language because quantitative data are currently lacking. This can lead to subjective and variable information requiring expertise of the caretaker for proper categorization of the condition through the use of evidence-based diagnostic tools including guidelines and algorithms (van den Heijkant and Bogaert, 2017). Of particular relevance is the age of the child when applying terminology to describe pediatric LUT function. The reference point used by the ICCS is 5 years of age or older (4 years of age for bowel dysfunction), because this age is used by the *Diagnostic and Statistical Manual of Mental Disorders,* 5th Edition (DSM-V) (American Psychiatric Association, 2013) and the International Classification of Diseases 10 (ICD-10) to characterize urinary incontinence disorders (World Health Organization, 2008). The ICCS terminology document authors do stipulate, however, that there is variability and maturational aspects that certainly will affect LUT function and that there are, in fact, children who have voluntary control over LUT function before 5 years of age. As a result, it is at the discretion of the provider to selectively apply these terms in younger cohorts of children. **(See the Terminology Document by Austin et al. [2014] for specific terms and their definition.)**

Daytime Urinary Incontinence and Bladder Dysfunction

Treatment

The ICCS has published treatment guidelines on various LUT conditions and their associated comorbidities (Austin et al., 2014; Burgers et al., 2013b; Chase et al., 2010; Franco et al., 2013; Hoebeke et al., 2010; Yang et al., 2018). **The management of a child or adolescent who suffers from LUTD is primarily directed at improving symptoms (e.g., urinary and/or fecal incontinence, recurrent UTIs) and protecting the upper urinary tract from permanent damage.** Methods for treating children with BBD must be tailored to the specific LUTD and the child's symptomatology. Therapeutic considerations include the underlying cause, patient age, motivation and maturity level, symptom severity and duration, prior interventions, and potential risk factors for upper urinary tract damage (i.e., elevated intravesical storage pressures, VUR, recurrent UTIs).

We use a stepwise approach to the treatment of children presenting with symptoms concerning for BBD (Thom et al., 2012). Our algorithm generally moves from least to most invasive with conservative measures (e.g., treatment of constipation, behavior modification) exhausted before initiating medications, physical therapy, biofeedback, neuromodulation, or surgical intervention.

According to the ICCS, researchers and/or clinicians should recognize three basic principles of treatment outcomes (Austin et al., 2014). First, the symptom *frequency* during baseline and after treatment each should be documented. Second, the assessment of treatment response must be based on *pretreatment baseline* registration symptom frequency. Third, the response *during* treatment should be noted, as well as the response *after cessation* of treatment for a *specified period;* and these two responses may not be the same. This has been outlined as follows:

- **Initial success** (based on symptom frequency)
  - No response: Less than 50% reduction
  - Partial response: 50% to 99% reduction
  - Complete response: 100% reduction
- **Long-term success**

- Relapse: More than one symptom recurrence per month
- Continued success: No relapse in 6 months after cessation of treatment
- Complete success: No relapse in 2 years after cessation of treatment

Urotherapy

Urotherapy is conservative-based therapy and treatment of LUTD that rehabilitates the LUT and encompasses a very wide field of health care professionals (Austin terminology document [Austin et al., 2014]). It primarily involves behavior modification of voiding (i.e., timed voiding schedules), lifestyle modification, and treatment of constipation. Although there are no randomized controlled trials comparing the efficacy of conservative intervention to other therapies, several retrospective studies suggest a reduction in symptoms of up to 70% with a strictly conservative approach (Allen et al., 2007; Wiener et al., 2000).

Urotherapy can be divided into standard therapy and specific interventions. **Standard components** include the following:

1. *Information and demystification*. It is often helpful to explain normal LUT function to parents and children and how the particular child deviates from normal.
2. *Instruction* on how to resolve LUTD (i.e., behavior modification, timed voiding, treatment of constipation).
3. *Lifestyle advice*. Encompasses balanced fluid intake and diet modification; diminished dietary irritants such as caffeine, carbonation, citrus, chocolate, and spicy foods; regular bladder- and bowel-emptying patterns; and skin care for those with perineal irritation from incontinence. It is also helpful to review optimal posture during voiding (i.e., sitting in the middle of the toilet with heels flat on the ground or supported on a footstool). One useful aid to teach correct upright posture is to have children straddle the toilet seat and face the toilet bowl during voiding, because this spreads the legs apart (preventing holding maneuvers such as forcefully crossing the legs) and forces them to straighten the back as they balance themselves on the toilet seat. This maneuver also can be used to successfully correct vaginal reflux.

4. *Registration* of symptoms and voiding habits, using bladder diaries or frequency-volume charts and potentially mobile applications.
5. *Support* and *encouragement* via regular follow-up with the caregiver.

Specific interventions of urotherapy include various forms of pelvic floor muscle retraining (i.e., biofeedback), neuromodulation, and intermittent catheterization.

In a randomized controlled trial of 150 patients with BBD, Braga et al. (2017) found that using bladder-training videos was similarly effective to the use of urotherapy in reducing symptoms at 3-month follow-up. Brownrigg et al. (2017) performed an assessment of QoL in the same group of patients. QoL changes from baseline were similarly significant with both the bladder-training video and urotherapy at time of follow-up. Bladder training is therefore considered a noninferior method to standard urotherapy in improving QoL.

Conservative Management

Bowel Dysfunction

One of our first steps is to decipher whether concomitant bowel dysfunction exists based on history, physical examination, and pelvic ultrasonography. As mentioned earlier, anorectal and LUT function are closely interrelated. If evidence of bowel dysfunction is indeed present (as is often the case), we generally initiate a bowel regimen that includes high fiber and increased fluid intake. Our rule of thumb for **daily fiber intake is age in years plus 15 to 20 for total number of grams to be ingested. Parents are reminded that without concurrent increased fluid intake, increased fiber could actually make matters worse by allowing smaller stool balls to bind together and subsequently increase the severity of their child's constipation.**

If increased fiber is not a feasible solution, we usually recommend titrating polyethylene glycol such that children are eventually having daily Bristol type 4 stools. In severe cases, we recommend a complete bowel cleanse (i.e., chemical disimpaction) consisting of what we term “magic mousse” supplementing with tap water enemas to relieve any distal obstruction by impacted stool in the rectal vault. Magic mousse consists of three simple ingredients: 1 cup ice cream, 1 cup prepared pudding, 6 oz. mineral oil, that are mixed and frozen (Campigotto, personal communication, 2014). Children younger than 6 years of age are given 60 mL twice daily, and those 6 years of age or older receive 120 mL twice daily.

This is generally done over a weekend for children who are in school or daycare because this routine is fairly intense and children may have multiple, somewhat unpredictable bowel movements. **It is imperative that the bowel regimen be continued throughout the treatment course to both maximize therapeutic efficacy for the bladder dysfunction component and counteract the constipating side effect of anticholinergic medications.**

The importance of addressing constipation in those with BBD is substantiated by the findings of a large retrospective study of 234 chronically constipated and encopretic children who were treated for constipation and reassessed at least 12 months after initiation of therapy (Loening-Baucke, 1997). Of these children, 29% complained of daytime urinary incontinence, and 34% had enuresis. UTI was present in 11% of the cohort and was more common in girls. **Relief of constipation resulted in disappearance of daytime urinary incontinence in 89% and enuresis in 63% of patients. There were no reported UTIs in any patient who had no anatomic abnormality of the urinary tract.**

Behavior Modification

The ultimate goal of any structured behavior modification program is to return the child to normal micturition habits. With this goal in mind, it is important to set an individualized voiding regimen to establish a consistent voiding routine. **The classic regimen entails *timed voiding* with frequent voids scheduled every 2 hours during the day.** This strategy is crucial in aiding to avoid bladder overactivity and urge symptoms, which can occur as the bladder fills and begins to reach the critical volume that triggers the urge to void. We recommend wristwatch alarms to all patients because these can readily assist older, more independent children to comply with timed voiding (Hagstroem et al., 2010). The use of a vibratory watch is also a good option because it does not disturb peers, with only the patient knowing that it has indicted the set time. Regardless of what regimen is used, children are encouraged to urinate before they have a sense of urgency, empty their bladders completely, and avoid abdominal straining.

The timed voiding regimen is often linked to a positive reinforcement program using a diary in which the child tracks the number of times voided during the day. It has been demonstrated that the establishment of a reward system can significantly improve the child's self-esteem and compliance (Allen et al., 2007). Specifically, the incentive scheme should focus on rewarding the child for following the recommended program (e.g., stickers each time the child voids during the day) as opposed to “not wetting” themselves. Not surprisingly, behavior modification has been shown to be more successful in older children (older than 8 years of age), who, in general, will be more motivated by peer pressure and are mature enough to respond to and follow instruction (Curran et al., 2000; Heilenkötter et al., 2006).

Biofeedback

Biofeedback is a treatment modality that uses electronic or mechanical instruments to relay perceptual evidence to assist a person in gaining control over a physiologic process or function (Liberati, 2005). This method has been used for over three decades in the urologic setting and employs noninvasive urodynamic instrumentation to measure, record, and provide direct, instantaneous information to the child about voiding function (Maizels et al., 1979). Real-time uroflowmetry allows the patient to observe the urine flow rate. Concurrent placement of adhesive pads on the perineum measures sphincter and/or pelvic floor activity. Abdominal electromyography (EMG) also can be performed if desired. Each session lasts approximately 45 minutes with a trained practitioner overseeing therapy. The visual and auditory feedback allows the child to become aware of and gain control over LUT function by teaching them how to voluntarily relax their sphincter and pelvic floor musculature during voiding, thus preventing detrusor-sphincter dyscoordination. In fact, many biofeedback programs have been tailored to children by using interactive computer games controlled by pelvic floor contraction and relaxation along with urinary flow rate (McKenna et al., 1999). This system has facilitated the training process and lowered the age at which children can be successfully treated; however, one should bear in mind that most children younger than 5 years of age are typically incapable of receiving biofeedback regularly.

A number of observational studies have documented the utility of biofeedback therapy in reducing the symptoms associated with LUTD (Chin-Peuckert and Salle, 2001; Klijn et al., 2006; Nelson et al., 2004; Yamanishi et al., 2000), expediting the resolution of VUR (Kibar et al., 2007; Palmer et al., 2002), and eliminating recurrent UTIs (Nelson et al., 2004). In a systematic review evaluating the efficacy of biofeedback in the treatment of children with BBD, 27 pooled studies (1 randomized controlled trial and 26 case series) showed an 83% and 80% improvement in UTI and daytime urinary incontinence, respectively (Desantis et al., 2011). The only included randomized study favored biofeedback over standard urotherapy (relative risk [RR] 1.4, 95% confidence interval [CI]

0.98 to 2), but this was not statistically significant. On analysis of all included studies, there also was improvement in constipation (18% to 100%), frequency (67% to 100%), urgency (71% to 88%), and VUR (21% to 100%).

A study evaluating the use of biofeedback in children for treatment of refractory OAB and dysfunctional voiding found that children with dysfunctional voiding have a better improvement of symptoms than children with OAB, although biofeedback was an effective treatment in both groups (Tugtepe et al., 2015). Three months of biofeedback in children with dysfunctional voiding resulted in improvement in UTIs, urge incontinence, fractionated voiding, constipation, voided volume, maximum flow rate, average flow rate, and postvoid residual (PVR), and children with OAB only improved maximum flow rate, average flow rate, voiding time, and PVR. As a single first-line treatment, Alyami et al. found biofeedback to be a potentially effective treatment for children with dysfunctional voiding and diurnal enuresis. In a cohort of 61 patients (52 with diurnal enuresis, 16 with UTI, and 38 with voiding discomfort), 77% were satisfied, with a disappearance of EMG signals in 65.5% after 6 months of biofeedback treatment (Alyami et al., 2018). A more recent systematic review evaluating the effectiveness of biofeedback in voiding dysfunction looked at 12 studies and also found biofeedback to be moderately successful in treating bladder and bowel dysfunction when used in conjunction with behavior modification (Tremback-Ball et al., 2018). In contrast with the studies mentioned earlier, Fazeli et al. did not find evidence to support the effectiveness of biofeedback in management of children with non-neuropathic voiding disorders after conducting a systematic review of five eligible studies. The results of this review concluded that there was no significant difference in the mean maximum urinary flow rate or likelihood of urinary infection compared with the control group, and the proportion of cases with resolved incontinence at 6 months was similar between the biofeedback and control groups (Fazeli et al., 2015). Fernandez-Ibieta and Ayuso-Gonzalez reviewed the efficacy of biofeedback in voiding dysfunction and noted the absence of PVR at the end of treatment and adequate or aggressive constipation management as a variable associated with clinical success (Fernandez-Ibieta and Ayuso-Gonzalez, 2016).

Clean Intermittent Catheterization

Lapides et al. (1972) first introduced the concept of clean intermittent catheterization (CIC) as a method of emptying the bladder in neurologically impaired patients. Since its initial description, this treatment strategy has gradually been employed in neurologically intact individuals with various types of LUTD. In the setting of dysfunctional voiding and in children who postpone micturition, the detrusor muscle stretches and the bladder becomes chronically overdistended. This repeated action over time can lead to two types of changes of the detrusor muscle: (1) bladder wall thickening caused by hyperplasia and hypertrophy resulting in OAB or (2) an underactive bladder with the end result of myogenic failure. In these cases, bladder emptying is often incomplete, resulting in large PVR urine volumes, urinary incontinence, and recurrent UTIs from stasis. CIC is a safe, effective, and well-tolerated treatment strategy to attain continence and reduce the rate of recurrent UTI in children with LUTD (Pohl et al., 2002). It is particularly crucial to discuss the merits of this intervention with sensate patients and their families to maximize adherence.

Pharmacotherapy

Pharmacologic intervention in the treatment of children with LUTD has traditionally encompassed anticholinergic agents and α-adrenergic receptor antagonists (i.e., α-blockers) to enhance bladder filling and emptying, respectively. We will generally initiate one or both of these medications once all other conservative measures have been exhausted. In some instances, we will start α-blockers concomitantly with biofeedback, and this management decision is ultimately left up to the discretion of the provider.

Anticholinergic Agents

Anticholinergics (i.e., antimuscarinics) are the current gold standard in the treatment of patients with symptoms referable to OAB. Muscarinic receptors are found in the human detrusor muscle, and bladder contractions are initiated by stimulation of these receptors with the release of acetylcholine from cholinergic nerves. The main action of anticholinergics is on the M1 and M3 receptor subtypes, which are thought to be responsible for the pathogenesis of detrusor overactivity (Chapple et al., 2002). **These agents act by reducing the frequency and intensity of uninhibited detrusor contractions during the filling phase of the bladder, resulting in an increase in functional bladder capacity and compliance** (Finney et al., 2006; Nijman, 2004). The clinical efficacy depends on various factors such as receptor affinity, pharmacokinetics, and the specificity for the bladder.

Oxybutynin was among the first generation of modern antimuscarinic medications available for treating incontinence in children. Five anticholinergic agents are currently approved in the United States for the treatment of OAB (darifenacin, oxybutynin, solifenacin, tolterodine, and trospium), with only two of these (oxybutynin and tolterodine) having formally achieved approval for use in children. Oxybutynin has antimuscarinic, antispasmodic, and analgesic properties. It causes the antispasmodic effect by acting as a calcium channel blocker. The analgesic and antispasmodic properties make the medication particularly attractive; however, these effects occur only with supraphysiologic doses that would render them useless secondary to side-effect profile (Chapple, 2000).

The nonselective pattern of activity and penetration of the blood-brain barrier are known to induce systemic and central side effects, respectively. The longer-acting extended-release formulation (Oxybutynin XL) is also approved by the U.S. Food and Drug Administration (FDA) for use in children and uses a novel delivery system resulting in absorption in the large intestine (Youdim and Kogan, 2002). **The main side effects include constipation, dry mouth, blurred vision, reduced sweating, flushing, and altered behavior and cognition. Oxybutynin is lipid-soluble and therefore likely to cross the blood-brain barrier** and in adults has been reported to interfere with cognition. However, in a nonrandomized trial of 25 children, Sommer et al. (2005) found that treatment with oxybutynin was not associated with cognitive impairment. Additionally, in a study by Veenboer et al. (2013), no significant differences in behavior were found between children with spinal dysraphism with and without long-term use of antimuscarinics.

Other methods of delivery of oxybutynin are intravesical and transdermal. These delivery systems avoid first-pass metabolism in the liver, leading to a decrease in the active metabolite *N*-desethyloxybutynin, thought to be responsible for many of the adverse effects associated with the use of oxybutynin. Intravesical delivery in the non-neurogenic, sensate population is limited, however, because of the need for catheterization. **The transdermal patch is as efficacious as the immediate-release oral form but with nearly one-half the incidence of dry mouth** (Davila et al., 2001)**. Local skin erythema and pruritus are side effects unique to this route of administration that can be seen in over one-third of patients** (Gleason et al., 2014).

The ideal patient for treatment of OAB with anticholinergics is the small-capacity, OAB with complete emptying. In children with significant PVR and incomplete emptying, anticholinergic treatment for OAB is not as efficacious, and therapy should be aimed at improving emptying and avoidance of overdistension that may be responsible for the OAB symptoms (Thom et al., 2012). In a retrospective analysis of children first prescribed anticholinergic substances for OAB between 2007 and 2008, Blais et al. (2016) determined that after 4 years of treatment, rates of discontinuation of antimuscarinic therapy in children were comparable to those reported in adults however, children persisted on the medication for longer.

α-Adrenergic Receptor Antagonists

α-Adrenoreceptors have been demonstrated in the LUT, with a large concentration located at the bladder neck and urethra (Ek, 1978). **α-Adrenergic blockade results in smooth muscle relaxation and decreased bladder outlet resistance.** Limitations of early α-adrenergic receptor antagonists (α-blockers) included their side-effect profile with hypotension and dizziness. With subsequent development of more “selective” α-blockers in the 1980s that targeted α_{1A}-adrenergic receptors rather than both α_{1A}- and α_{1B}-adrenergic receptors, these side effects were greatly diminished. Examples of selective α-blockers include alfuzosin, doxazosin, prazosin, silodosin, tamsulosin, and terazosin.

Currently, α-blockers are a mainstay drug used to facilitate bladder emptying in the adult population, particularly in adult males with benign prostatic hyperplasia. Early work on the benefits of α-blockers on pediatric LUTD by Austin et al. (1999) pioneered the introduction of α-blockers into the armamentarium of drugs that can be used to treat voiding issues in children. In this pilot report, there was an 82% improvement in the measured parameters of 17 patients treated with α-blocker therapy. In a follow-up of their initial study, the group continued to see improvement in multiple LUTS, daytime incontinence episodes, and PVR measurements in 55 children treated with doxazosin for dysfunctional voiding (Cain et al., 2003).

Kramer et al. (2005) conducted the first randomized, placebo-controlled study of selective α-blocker therapy in children with dysfunctional voiding. In this study, 38 children were randomized to either placebo or 0.5 mg of doxazosin. Unlike in previous studies, they found no significant difference in the PVR and uroflow measurements between the treatment groups. There was a trend toward a significant improvement in urinary incontinence (4 vs. 14 incontinent episodes per week from a median baseline of 18 weekly episodes) and the DVSS parental survey in the α-blocker group compared with the placebo group. There was a significant difference in parental satisfaction, with a higher parental satisfaction in the children treated with α-blockade.

Vanderbrink et al. (2009) reported an observational study of 23 children with bladder neck dysfunction who were treated for an average of 10 months with tamsulosin. The number of incontinent episodes decreased from over 5.5 to less than 1 episode on average per day. In addition, increases in Qavg and Qmax and a reduction in PVR urine and abnormal uroflow patterns were observed during therapy. The safety profile for α-blockade in this pediatric population also was assessed, and the results were consistent with those in other reports using selective α-blockers in children. Although orthostatic hypotension was not formally evaluated, the authors did not find any significant alterations of blood pressure measurements, and there were no reports of any symptomatology suggestive of hypotension.

α-Blocker treatment selection of children with LUTD is done through a comprehensive treatment program that involves an escalating treatment paradigm (Chase et al., 2010; Thom et al., 2012) or identifying patients with characteristic uroflow abnormalities (Van Batavia et al., 2010). The uroflow finding of a prolonged “EMG lag time” is associated with bladder neck and internal urethral sphincter discoordination and may be used to select patients for α-blocker therapy (Van Batavia et al., 2010, 2011). The EMG lag time is the time duration after the external sphincter relaxes and the flow of urine. A prolonged lag time of greater than 6 seconds is suggested as a reliable indicator of tailoring LUTD treatment with α-blocker therapy (Van Batavia et al., 2014). Further validation is needed to investigate the reliability and reducibility of these uroflow findings.

Botulinum Toxin

A relatively recent investigational pharmacologic approach in refractory cases of LUTD is botulinum neurotoxin type A (BoNTA). The toxin acts by inhibiting acetylcholine (ACh) release at the presynaptic neuromuscular junction. Inhibited ACh release results in regionally decreased muscle contractility and atrophy at the injection site. The chemical denervation that ensues is a reversible process, and eventually the toxin is inactivated and removed. Clinical effects begin within 5 to 7 days of injection, with maximal effects reached within 4 to 6 weeks (Gamé et al., 2009). The duration of induced paralysis varies depending on the type of muscle treated, with duration of treatment effect lasting between 3 and

12 months (Riccabona et al., 2004).

Clinically, BoNTA injections have been used safely in the treatment of a number of clinical disorders (Maria et al., 2005), including neurogenic LUTD (Gamé et al., 2009). BoNTA has been subsequently applied to non-neurogenic LUTD, and there are a number of reports of BoNTA used to treat children with OAB and dysfunctional voiding (Franco et al., 2007; Hoebeke et al., 2006; Mokhless et al., 2006; Petronijevic et al., 2007; Radojicic et al., 2006; Steinhardt et al., 1997; Vricella et al., 2014). BoNTA is directly injected into the detrusor muscle (in patients with OAB) or external urinary sphincter (in patients with dysfunctional voiding) under cytoscopic guidance. One of the main drawbacks of this therapeutic modality is the need for retreatment given the reversible nature of this chemical denervation secondary to synaptic terminal resprouting within 6 months of injection. Fortunately, preliminary studies suggest that repeated BoNTA injections are safe in children and do not induce additional fibrosis in the bladder wall (Pascali et al., 2011). In a retrospective review of 20 patients evaluating outcomes of BoNTA in the external urethral sphincters from 2010 to 2013, 't Hoen et al. (2015) found PVR to be decreased by 75%. Furthermore, 16 patients achieved complete dryness, and 5 of 11 patients improved in frequency of UTI.

Neuromodulation

During the past two decades, electrical nerve stimulation, also known as *neuromodulation*, has been applied to the treatment of non-neurogenic LUTD in children (Table 35.1). Several of the reported changes after treatment with neuromodulation include significantly increased bladder capacity, decreased severity of urgency, improved continence, and decreased UTIs (Bower et al., 2001; Hoebeke et al., 2001b; Roth et al., 2008). A significant improvement in urodynamic parameters of bladder compliance, number of involuntary contractions, and bladder volume at first detrusor contraction also has been noted (De Gennaro et al., 2004).

Stephany et al., 2013	SNM	BBD	14	S3	Not stated

BBD, Bowel-bladder dysfunction; *DV,* dysfunctional voiding; *ES,* electrical stimulation; *LUTD,* lower urinary tract dysfunction; *mo,* month; *OAB,* overactive bladder; *PTNS,* percutaneous tibial nerve stimulation; *SNM,* sacral nerve modulation; *TENS,* transcutaneous electrical nerve stimulation; *UI,* urinary incontinence; *UR,* urinary retention.

In neuromodulation, electrical stimuli are exerted in a noninvasive manner to alter the existent neural transmission pattern and modulate detrusor activity. The putative mechanism involves acting centrally by rebalancing excitatory and inhibitory information and returning the neural drive toward a more neutral status. A number of modalities have been studied in children, including sacral neuromodulation, pudendal nerve stimulation, and tibial nerve stimulation. Although preliminary results have been promising, electrical nerve stimulation's role in children with non-neurologic LUTD is controversial because of the lack of controlled trials and largely obscure mechanism of action. Two randomized controlled trials, however, were performed using transcutaneous electrical nerve stimulation (TENS) for OAB (Lordelo et al., 2010; Quintiliano et al., 2015). Children were randomized to either parasacral TENS or scapular TENS (sham), and no significant improvement in bladder function or LUTS was seen in the sham group as compared with the parasacral TENS group (Lordelo et al., 2010). In the randomized intragroup and intergroup comparison trial between parasacral TENS and oxybutynin, parasacral TENS was as effective as oxybutynin in treating OAB in children (Quintiliano et al., 2015). With TENS, superficial electrodes are placed on each side of the S3 and S2 spinal cord segments. In general, therapy consists of 20-minute sessions three times per week. Percutaneous tibial nerve stimulation (PTNS) is performed with a 34-gauge stainless steel needle inserted approximately 5 cm cephalad to the medial malleolus, and a grounding pad is placed just posterior to the medial malleolus. Proper needle placement in children is confirmed by observing ipsilateral plantar and/or toe flexion or fanning. Although the purported mechanism of action differs somewhat, neuromodulation by PTNS is based on the traditional Chinese practice using the Sanyinjiao acupuncture point, which overlies the posterior tibial nerve (van Balken et al., 2004). The posterior tibial nerve is a mixed sensory and motor nerve originating from the L4 to S3 spinal roots that also contributes to sensory and motor control of the bladder, urinary sphincter, and pelvic floor musculature. Therapy has been invariably applied once weekly, usually for 30-minute outpatient treatment sessions. A prospective study of 69 children by Veiga et al. (2016) determined that a complete resolution of symptoms occurred within 10 to 20 sessions of TENS, with some patients experiencing complete resolution as early as the third session.

Since its initial description, a significant number of reports have been generated on sacral nerve root stimulation via implantable electrodes. In the past decade, sacral nerve modulation (SNM) has gained widespread recognition in adults and was approved by the FDA for use in urology for urinary urgency/frequency, urge incontinence, pelvic floor dysfunction, and nonobstructive urinary retention. Despite off-label use, a number of groups have reported on their experience with SNM in children with non-neurogenic LUTD (Humphreys et al., 2006; McGee et al., 2009; Roth et al., 2008; Stephany et al., 2013; Tanagho, 1992).

Before sacral implantation can be performed, percutaneous transforaminal access to the S3 spinal nerve must be achieved. Once the correct responses are obtained, the quadripolar tined lead of the neurostimulator device can be implanted. This lead can then be connected to an external neurostimulator device via a tunneled subcutaneous extender for programming and trial assessments. If this is successful, the patient undergoes a second procedure to implant the permanent neurostimulator device into a subadipose pocket in the upper gluteal region. Complications commonly cited with implantable SNM devices are device and/or wound infection, electrode migration, loss of effect, and lead fracture. Revision rates range between 7% and 18%, secondary to lead migration, faulty connection, and infection. In a prospective analysis of predictors of outcomes in 83 children with isolated OAB treated with parasacral TENS, Hoffmann et al. (2018) found a significant response to parasacral TENS treatment in 96.4% of cases, with complete resolution of symptoms achieved in 56.6% of cases. Nocturnal enuresis was identified as the only predictor of poor outcome after parasacral TENS, with only a partial resolution being observed in 54.5% of cases; no other factor was associated with response treatment.

Key Points: Management of Daytime Urinary Incontinence and Bladder Dysfunction

- The management of a child or adolescent with LUTD is primarily directed at improving symptoms (e.g., urinary and/or fecal incontinence, recurrent UTIs) and protecting the upper urinary tract from permanent damage.
- In general, a stepwise approach is used with an algorithm that progresses from least to most invasive with conservative measures (e.g., treatment of constipation, behavior modification) exhausted before initiating medications, physical therapy, biofeedback, neuromodulation, or surgical intervention.
- In one large study, relief of constipation alone resulted in the disappearance of daytime urinary incontinence in 89% and enuresis in 63% of patients studied (Loening-Baucke, 1997).
- Anticholinergics are the current gold standard in the treatment of patients with symptoms referable to OAB and ideally for patients with efficient bladder emptying with low PVR. These agents act by reducing the frequency and intensity of uninhibited detrusor contractions during the filling phase of the bladder, resulting in an increase in functional bladder capacity and compliance. The main side effects include constipation, dry mouth, blurred vision, reduced sweating, flushing, and altered behavior and cognition.
- α-Adrenergic blockade results in smooth muscle relaxation and decreased bladder outlet resistance to facilitate bladder emptying.
- In neuromodulation, electrical stimuli are exerted in a noninvasive manner to alter the existent neural transmission pattern and modulate detrusor activity. The putative mechanism involves acting centrally by rebalancing excitatory and inhibitory information and returning the neural drive toward a more neutral status. A number of modalities have been studied in children, including SNM, pudendal nerve stimulation, and tibial nerve stimulation.

Special Conditions of Lower Urinary Tract Dysfunction and Their Treatment

Giggle Incontinence (Enuresis Risoria)

Enuresis risoria is an uncommon form of daytime incontinence classically seen in school-age females. Typically, moderate-to-large amounts of urinary leakage are triggered by laughing alone. The accepted theory is that of a central nervous system (CNS) inactivation (i.e., cataplexy) in association with laughter resulting in urinary incontinence (Sher and Reinberg, 1996). It should be emphasized that the incontinence episodes are invariably significant, and often the entire bladder volume is drained. Daytime urinary incontinence in conjunction with laughter is also seen in children with OAB and is more common than true giggle incontinence. It is a diagnosis of exclusion, and it is usually established on history and supplemented by the absence of other voiding symptoms and normal investigations. Giggle incontinence has a significant adverse effect on the social life, and this is often why medical assistance is sought. Currently, available treatment strategies include biofeedback or methylphenidate (Berry et al., 2009; Richardson and Palmer, 2009).

Pollakiuria (Extraordinary Daytime Urinary Frequency)

This is a disorder characterized by a very high daytime frequency of micturition (sometimes as high as 50 times per day). A key aspect of this syndrome, which differentiates it from OAB and often can clinch the diagnosis, is that the symptoms are limited only to the daytime. It is seen in early childhood (4 to 6 years of age) in both genders and associated with a history of recent death or life-threatening event in the family. Usually it runs a benign, self-limited course over a period of approximately 6 months (Bergmann et al., 2009). No specific treatment, apart from reassurance, is necessary. Children presenting with frequency, however, merit clinical investigation to exclude other pathologic causes.

Underactive Bladder

As the name suggests, underactive bladder describes a child who is required to raise intra-abdominal pressure to initiate, maintain, and complete voiding. Once a functional or anatomic cause for bladder outlet obstruction has been ruled out, there are two main approaches to this entity. The first is with timed voiding and double voiding to more efficiently empty the bladder and lower the ultimate PVR volume of urine. If this treatment strategy fails to achieve the desired effect, we often recommend CIC with frequency dependent on symptom severity. Obviously, this requires appropriate counseling and thoughtful guidance of both the patient and caregiver, especially in the child who is neurologically intact.

Vaginal Reflux (Vaginal Entrapment and Vaginal Voiding)

Vaginal reflux is characterized by incontinence after normal voiding in the absence of other LUTS. It is commonly seen in prepubertal girls, and the typical history is that of wetting of undergarments approximately 10 to 15 minutes after a normal void. It often can be associated with labial adhesions as a result of chronic irritation and inflammation from skin exposure to relatively caustic urine. Reassurance and postural modification to ensure complete vaginal emptying is the only treatment required.

Enuresis

Over the past several decades, much has changed in our understanding of enuresis. Previous notions of voluntary control have been replaced by an appreciation of genetic and pathophysiologic mechanisms. What is known with certainty is that enuresis is a common medical condition in children (Shreeram et al., 2009). It affects millions of children throughout the world and is associated with a significant negative impact on self-esteem and health-related QoL (Wolfe-Christensen et al., 2013).

Terminology and Background

The term *enuresis* is synonymous with *nocturnal enuresis* and is defined as discrete episodes of urinary incontinence during sleep in children older than 5 years of age in the absence of congenital or acquired neurologic disorders. The term *diurnal enuresis* has been eliminated completely. The child who wets during the day and night can be said to have daytime urinary incontinence and enuresis or nonmonosymptomatic enuresis.

Enuresis is categorized as monosymptomatic enuresis (MSE) or nonmonosymptomatic enuresis (NMSE). ***MSE* is defined as enuresis in children without any other LUTS and without a history of bladder dysfunction. MSE is further subdivided into *primary* and *secondary* forms. Children who have *never* achieved a satisfactory period of nighttime dryness (~80% of enuretic children fit this definition) have primary MSE** (Friman and Warzack, 1990)**. Children who develop enuresis after a dry period of at least 6 months are said to have secondary enuresis** (von Gontard and Nevéus, 2006). Secondary enuresis often is ascribed to an unusually stressful event (e.g., parental divorce, birth of a sibling, sexual abuse); an organic cause (e.g., UTI, diabetes, obstructive sleep apnea, neurogenic bladder); or a psychological cause (e.g., ADHD or conduct disorder) at a time of vulnerability in a child's life. These children are more likely to have NMSE (see next paragraph) and do not respond as well to treatment. The exact cause of secondary MSE, however, remains largely unknown. The clinical presentations of children with primary and secondary MSE are otherwise similar, which suggests a common pathogenesis (Robson et al., 2005). Moreover, large family studies have demonstrated that secondary MSE is usually no different etiologically from primary MSE, with undue emphasis on their difference being unwarranted (Schaumburg et al., 2008).

Enuresis with any daytime LUTS is defined as NMSE (Franco et al., 2013). Daytime LUTS suggesting NMSE include daytime incontinence (not obligatory), frequency, genital or LUT pain, and holding maneuvers (i.e., strategies to postpone voiding). A careful history is often required to elicit these symptoms, which usually indicate either OAB (i.e., a storage issue) such as urgency, or dysfunctional voiding (i.e., emptying problems) such as hesitancy, straining, weak stream, intermittency, or a feeling of incomplete emptying.

The pathogenesis, evaluation, and treatment of MSE and NMSE overlap considerably (Nevéus et al., 2010). Approximately 15% to 30% of enuretic children experience daytime LUTS; however, these reported numbers are likely grossly underestimated (Gumus et al., 1999; Järvelin et al., 1988). In fact, **most experts in the field would estimate the proportion of children with enuresis that are truly monosymptomatic to represent fewer than one-half of all bedwetting children** (Franco et al., 2013).

Our initial approach to NMSE is nearly identical to our approach for children with LUTD. Obviously one begins with a thorough history and physical examination, along with the appropriate laboratory and imaging studies. In terms of NMSE therapy, we also begin by identification and treatment of constipation. As discussed earlier in this chapter, effective treatment of bowel problems can lead to the spontaneous remission of daytime incontinence (Loening-Baucke, 1997). We also will treat the underlying LUTD symptoms first, because effective treatment of OAB (or dysfunctional voiding) can lead to cessation of the enuresis entirely (Franco et al., 2013). If comorbid behavioral disorders are present, these should be addressed by an appropriate provider. If enuresis persists after the previously mentioned interventions, standard treatment for MSE can follow. The remaining section of this chapter will focus specifically on MSE and its epidemiology, cause, evaluation, and treatment strategies.

Epidemiology and Natural History

Enuresis is a common problem, with an estimated 7 million children in the United States alone with this condition. According to a recent large longitudinal study in the United Kingdom, at least 20% of children in the first grade occasionally wet the bed, and 4% wet the bed two or more times per week (Butler and Heron, 2008). Prevalence varies with age, suggesting an immaturity of the LUT and nervous system (Fig. 35.1). In a study of almost 11,000 children in the United States, the prevalence of enuresis in boys at 7 and 10 years of age was 9% and 7%, respectively, and in girls at those ages it was 6% and 3%, respectively (Byrd et al., 1996). It is currently generally accepted that in the West **approximately 15% of children will have some degree of nighttime wetting at 5 years of age, with a spontaneous resolution rate of approximately 15% per year** (Forsythe and Redmond, 1974)**. Consequently, at 15 years of age only 1% to 2% of teenagers will still wet the bed** (Klackenberg, 1981). It has also been shown that **the longer the enuresis persists, the lower the probability is that it will resolve spontaneously** (Bakker et al., 2002; Forsythe and Redmond, 1974).

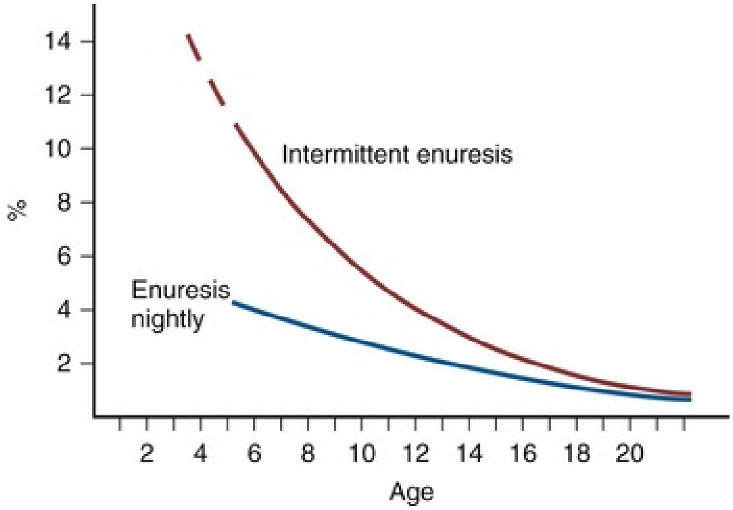

FIG. 35.1 Prevalence rate of enuresis from childhood through young adulthood. (From Austin PF, Nevéus T. Evaluation and management of enuresis. *AUA Update Series* 2012;XXI.)

Enuresis seems to be more common in boys than in girls, with most reports revealing a 2:1 ratio. Although this finding has been disputed by other groups, it is well accepted that by adolescence the prevalence in both males and females reaches equipoise (Yeung et al., 2004).

Enuresis is also known to be common in children with comorbid behavioral issues such as ADHD, oppositional-defiant disorder, conduct disorder, anxiety, and depression (Baeyens et al., 2004; von Gontard et al., 2011). It is estimated that 20% to 30% of children with enuresis have comorbid clinical behavioral disorders that fulfill the criteria for *DSM-V* psychiatric disorders and may subsequently have a negative impact on compliance and ultimate outcome if left untreated (von Gontard et al., 2011).

Genetics

Enuresis has a complex and multifactorial pathophysiology with a strong genetic underpinning (Schaumburg et al., 2008; von Gontard et al., 1998a). When one or both parents have a history of prolonged nighttime wetting, approximately 43% and 77%, respectively, of the offspring will be affected (Bakwin, 1973). When neither parent has a history of nocturnal enuresis, only 15% of offspring will be affected (Bakwin, 1973). Moreover, the concordance among monozygotic twins is almost twice that among dizygotic twins (68% vs. 36%) (Bakwin, 1971). **Linkage of enuresis to markers on chromosomes 12, 13, and 22 has been reported, with autosomal dominant inheritance and high penetrance suggested; however, a major gene locus has yet to be identified** (Arnell et al.,1997; Eiberg 1998; Eiberg et al., 1995). Family and twin studies suggest locus heterogeneity and poor phenotype-genotype correlation (von Gontard et al., 2011). The identification of these genes certainly lifts the burden of guilt from children who have enuresis and helps dispel the theory that enuresis is behavioral in origin and completely under their control.

Pathophysiology

It is generally accepted that **enuresis stems from a maturational delay in the ultimate development of bladder control** (Järvelin, 1989; Light, 1998). This contention is rooted in the fact that most children eventually attain nocturnal dryness regardless of what intervention is used and even if enuresis is left untreated. The hypothesis that there is a difference in the CNS maturation in children with primary enuresis compared with controls is supported by neurophysiologic data (Iscan et al., 2002). Many children who have enuresis are noted to have progressive maturation of bladder stability in conjunction with electroencephalography (EEG) findings that suggest increased CNS recognition of bladder fullness and the ultimate ability to suppress the onset of bladder contraction (Watanabe and Azuma, 1989). This would further lend credence to the premise that delayed maturation of bladder control plays a role in MSE.

Put very simply, **the three organ systems implicated in the pathogenesis of enuresis include the bladder (i.e., a reduced nocturnal bladder capacity)** (Yeung et al., 2002), **the kidney (i.e., nocturnal polyuria)** (Nørgaard et al., 1989a; Vande Walle et al., 2007), **and the brain (i.e., a disorder affecting arousal from sleep)** (Iscan et al., 2002; Watanabe and Azuma, 1989). Enuresis is logically thought to result from a disruption or maturational lag in one or more of these critical domains (Fig. 35.2).

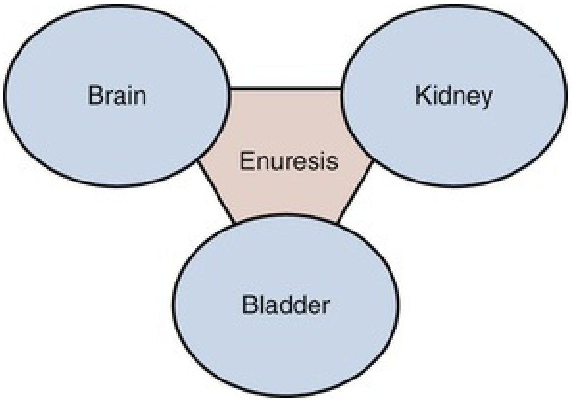

FIG. 35.2 Organ system involvement in pathogenesis of enuresis.

Bladder Overactivity and Reduced Nocturnal Bladder Capacity

There seems to be a subset of children with primary MSE who have nocturnal bladder overactivity regardless of amount of urine production. Yeung et al. (1999) found that nearly one-half of treatment failures with standard therapy (i.e., desmopressin or moisture alarm) had normal daytime bladder function but marked detrusor overactivity during sleep that resulted in enuresis. Almost none of these children had nocturnal polyuria.

When urodynamic studies are performed during sleep, the only difference between children with and without MSE is the increased rate of bladder contractions that occur in association with the enuretic episode (Nørgaard et al., 1989b). In addition, urodynamic studies during sleep demonstrate a relationship between nocturnal enuresis and pelvic floor activity. When pelvic floor activity increased in association with detrusor contractions, wetting was usually avoided, and patients often would awaken subsequently to void. In contrast, when pelvic floor activity did not increase, the detrusor contraction usually was associated with a wetting episode (Nørgaard et al., 1989b).

Children with enuresis (even those without daytime symptoms) have been noted to have a smaller bladder capacity than age-matched controls (Starfield, 1967). The reduced bladder capacity appears to be functional rather than anatomic. This was illustrated by a study in which bladder capacity was measured in the awake state as well as under general anesthesia in children with enuresis and compared with functional bladder capacity among controls (Troup et al., 1971). Compared with controls, the average volume of urine voided by enuretic children in the awake state was reduced. However, when volumes were measured during general anesthesia, enuretic children had similar mean bladder volumes to awake controls. In a somewhat contradictory study, Kawauchi et al. (2003) found that the maximal endurable bladder capacity during the daytime was similar between children with enuresis and controls. However, among children with enuresis, the maximum voided volume during the night (measured using a diaper and enuresis alarm) was significantly smaller than the maximal daytime bladder capacity. They concluded that inability to hold urine during sleep may be an important factor in MSE. A number of trials have noted functional bladder capacity to be a strong predictor of response to desmopressin in MSE (Eller et al., 1998; Rushton et al., 1996). As a result, a refractory response to desmopressin may suggest either unrecognized nocturnal OAB or that the decreased nocturnal urine production elicited by desmopressin continues to overwhelm a functionally undersized bladder. A recent study found that there is a reduction of the nocturnal bladder capacity in selected children despite normal daytime bladder function (Borg et al., 2018).

Whether this situation is a result of reduced nocturnal functional bladder capacity or nocturnal detrusor overactivity, however, may not be critical because the treatment strategy employed would largely be the same (i.e., anticholinergic medications).

Nocturnal Polyuria

Increased nighttime urine output appears to play an important role in nocturnal enuresis (Nevéus et al., 2010). In children and adolescents without enuresis, the diurnal pattern of urine production results in a relative reduction in nocturnal diuresis to approximately 50% of daytime levels (Rittig et al., 1995, 2010). The prevailing mechanism for how this occurs is thought to result from a nocturnal circadian peak of antidiuretic hormone (ADH) release from the posterior pituitary gland that regulates free water excretion. Other purported mechanisms for increased nocturnal urine production may include increased fluid intake before bedtime (Robson, 2001), a blunted response to ADH, increased evening dietary solute load with high nocturnal urine osmolarity (Dehoorne et al., 2006), abnormal renal sodium handling (related to release of angiotensin II, aldosterone, and natriuretic peptide), abnormal circadian rhythm of glomerular filtration rate (De Guchtenaere et al., 2007), abnormal sodium and calcium excretion (Raes et al., 2006), and obstructive sleep apnea/hypoventilation (Su et al., 2011).

Regardless of the mechanism, urine production that normally decreases at night secondary to these circadian systems fails to do so and will subsequently result in nocturnal polyuria, which can exceed the functional capacity of the bladder and result in an enuretic episode. Proof of this concept was demonstrated by Rasmussen et al. (1996), who were able to actually induce enuresis in normal healthy children by increasing nocturnal urine output. Despite this seemingly simple causal relationship, however, it is clear that nocturnal polyuria and ADH responsiveness are highly complex phenomena, because not all children with enuresis have nocturnal polyuria, and, in those who do, nocturnal ADH may be normal (Steffens et al., 1993). In fact, it has been observed that the urine osmolality of children with and without MSE is similar and that early morning osmolality tends to increase with age (Kawauchi et al., 1996). This suggests that the ADH secretion response may be a maturational one and lend further support to the maturation hypothesis.

Arousal and Sleep

Regardless of whether the child has detrusor overactivity and/or nocturnal polyuria, neither observation explains why a child with enuresis is unable to awaken from sleep to void before a wetting episode. Given that both bladder distention and detrusor contractions are robust arousal stimuli (Koyama et al., 1998), it is curious that an enuretic child will not wake up during the night to the sensation of a full or contracting bladder. Parents invariably describe their children with enuresis as excessively deep sleepers (Nevéus et al., 1999a; Wille, 1994). This situation is often experienced by family members of patients exposed to alarm therapy as parents awaken from sleep while their enuretic child will sleep through the alarm. Nevéus et al. (1999a) obtained questionnaire data from 1413 schoolchildren between 6 and 10 years of age and noted that enuresis was associated with subjectively high arousal threshold and significant confusion on awakening from sleep. Wolfish et al. (1997) performed a laboratory study of 33 boys 7 to 12 years of age (15 with enuresis and 18 age-matched controls) and found that attempts at arousal were more often successful in control subjects than in boys with enuresis (40% vs. 9%, respectively). In a comparison control study, sleep was investigated by one overnight video-polysomnography. Children with enuresis displayed higher sleep fragmentation and periodic limb movements in sleep than the control children with a possible sleep disorder without nocturnal enuresis (Dhondt et al., 2014). These findings emphasize the central involvement of the pathophysiology of nocturnal enuresis and the multifactorial nature of the condition.

A subjectively deep sleep, however, is not the same as an objectively deep sleep, as measured by EEG. Freitag et al. studied brainstem evoked potentials in 37 children with MSE and compared these children to 40 age-matched controls (Freitag et al., 2006). They found that interpeak latencies of the brainstem evoked potentials were increased in children with MSE, suggesting a maturational defect of the brainstem to account for this finding. Other sleep studies, however, show that sleep patterns among children with and without enuresis are similar (Bader et al., 2002; Ritvo et al., 1969). These studies indicate that enuretic episodes may occur at random throughout the night, but primarily during non–rapid eye movement (non-REM) sleep (Nevéus et al., 1999b) and when the bladder is at a volume equivalent to the maximal daytime functional capacity (Mikkelsen et al., 1980; Nørgaard et al., 1989b). A study of 35 children with therapy-resistant MSE in Hong Kong demonstrated that although appearing to be heavy sleepers, these children had, in fact, more overall light sleep (stage I/II non-REM) with sleep fragmentation, rather than deep sleep (stage III/IV non-REM). The cerebral cortex received afferent input of sleep OAB with frequent cortical arousals that failed to wake the children, which was presumed to be a paradoxic elevation in the conscious awakening threshold. OAB-associated cortical arousals may cause a shift from deep to light sleep but not to complete awakening, perhaps because of long-term overstimulation of the sleep arousal center by signals from the bladder. In summary, these studies suggest that children who wet the bed sleep normally (i.e., the distribution and proportion of the various stages of sleep are within normal limits) but are unable to awaken in response to nocturnal detrusor contractions or bladder fullness.

Evaluation

The basic evaluation of the child with MSE includes **history, physical examination, and urinalysis. The history, including a voiding diary, is the mainstay of the evaluation** (Nevéus et al., 2010; Robson, 2009). (See Chapter 28 and the discussion of bladder and bowel diaries earlier in this chapter.) **The**

principal objective of the evaluation is to rule out BBD (NMSE) or enuresis as a manifestation of an underlying medical disease (e.g., posterior urethral valves, spinal dysraphism, diabetes mellitus) and to identify that the enuresis is truly monosymptomatic. If there is BBD and the child has NMSE, treatment is aimed at BBD before consideration or initiation of therapy for MSE (Franco et al., 2013).

Once MSE is confirmed, it is often helpful to characterize the enuresis further, such as frequency and volume. Distinguishing between primary and secondary MSE should be attempted, mainly for prognostic purposes because treatment is generally the same. One important point to ask about is the presence of nocturia; this would suggest that the child is not extremely difficult to arouse from sleep. The social history is also particularly germane because somatic and psychological comorbid conditions are more common in children who were previously dry than in those with primary MSE (Robson et al., 2005). A family history of enuresis is often helpful in establishing a genetic pattern. Interventions the family has already tried also should be determined.

Treatment

Conventional therapies for enuresis include behavior modification, the enuresis "moisture" alarm, and pharmacologic therapy (e.g., desmopressin, anticholinergics, imipramine). The evidence for the efficacy of much of the care that we provide to children with enuresis is weak (Nevéus et al., 2010). Given the self-limiting nature of enuresis, one treatment option is to observe and allow the natural history to follow its predetermined course. However, enuresis that occurs as infrequently as once per month is associated with reduced self-esteem, and treatment has been reported to improve self-worth, regardless of the type or the success of therapy (Hägglöf et al., 1998; Longstaffe et al., 2000).

The decision about when to start treatment generally should be guided by the degree of concern and motivation on the part of the child rather than the parents. For the child, nocturnal enuresis usually becomes significant when it interferes with his or her ability to socialize with peers (e.g., sleepovers, summer camps) (Jalkut et al., 2001). **It is important to determine whether the child is mature enough to assume responsibility for treatment.** Treatment probably should be delayed if it seems that the parents are more interested in treatment than the child and the child is unwilling or unable to assume some responsibility for the treatment program. The child must be highly motivated to participate in a treatment program that may take months to achieve successful results. Although general advice should be given to all bedwetting children, active treatment should usually not be started before 6 years of age (Nevéus et al., 2010). However, age should not be the only criterion for initiation of active treatment. In a recent meta-analysis evaluating 18 RCTs with 1649 subjects, Song et al. concluded that desmopressin had a higher relapse rate with a comparable efficacy to bed alarm. A combination of desmopressin plus anticholinergic agent produced a better efficacy to desmospressin alone; however, a similar relapse rate was observed (Song et al., 2019).

Behavioral Therapy

Data from randomized trials on the efficacy of behavioral therapy are lacking (Caldwell et al., 2013; Pennesi et al., 2004), but clinical experience (i.e., level 4 evidence) suggests that this approach is beneficial (Nevéus et al., 2010). Likewise, although the influence of the clinician's behavior has not been formally studied, clinical experience suggests that the ability to establish a rapport with the child and to engender and sustain motivation is important for successful behavioral therapy. **The fundamental goal of behavioral therapy is much like the treatment of daytime urinary incontinence and centers around the practice of good bladder and bowel habits.**

Children should attempt to void regularly during the day and just before going to bed for a total of six to seven times daily. High-sugar and caffeine-based drinks should be avoided, particularly in the evening hours. Daily fluid intake should be concentrated in the morning and early afternoon, and both fluid and solute intake should be minimized during the evening. Isolated nighttime fluid restriction, without compensatory increase in daytime fluid consumption, may prevent the child from meeting his or her daily fluid requirement and is usually unsuccessful.

In practice, compliance improves when parents and children understand normal bladder function and the pathogenesis of enuresis. **Children should be reassured that enuresis is not their fault, and children should not be punished for bedwetting, because this practice is often counterproductive** (van Londen et al., 1993). An individualized program with a series of realistic goals between appointments and monthly follow-up to sustain motivation improves the outcome (Glazener and Evans, 2004). A personalized calendar for recording daytime incontinence and enuresis episodes and the frequency and timing of bowel movements aids the family and child to follow their progress.

When initiating active treatment for primary MSE, there is level 1 evidence to support the use of the enuresis alarm (Glazener et al., 2005)**, desmopressin** (Glazener and Evans, 2002)**, anticholinergics** (Austin et al., 2008)**, and tricyclic antidepressants (TCAs; e.g., imipramine)** (Glazener and Evans, 2000)**, either alone or in combination.** Generally, in addition to behavioral therapy, the two contemporary first-line therapies for MSE include the enuresis alarm and desmopressin. They are both valid treatment options, but patient, caregiver, and disease-related parameters exist that may aid in offering prognostic information in terms of which therapeutic modality should be first entertained (Fig. 35.3). **The enuresis alarm seems best fit for motivated families and for children without polyuria but with low PVR** (Nevéus et al., 2010)**. Desmopressin seems best suited for children with nocturnal polyuria and normal bladder reservoir function** (Hunsballe et al., 1998)**, those with infrequent wet episodes, and for families in whom alarm treatment has failed or who have refused alarm treatment** (Nevéus et al., 2010)**. Children in whom one first-line treatment has failed should be offered the other, and for those in whom both have failed, second- and third-line treatments can be tried, either alone or in combination (e.g., desmopressin plus oxybutynin).**

Enuresis Alarm

Alarm training has been shown to be the most effective long-term therapeutic modality in the treatment of MSE (Glazener et al., 2005). Alarms have been used since the 1930s and represent classic Pavlovian conditioning techniques, but exactly how the alarm works remains somewhat of a mystery because, strictly speaking, classical conditioning mechanisms should not be functional during sleep. Proposed mechanisms include suppression of bladder emptying during sleep, increasing nocturnal bladder volume (Hansen and Jørgensen, 1997), and waking to void by signaling when they urinate. Interestingly, most children who become dry with the use of the enuresis alarm actually sleep through the night and do not necessarily wake to void. The response is more gradual and sustained than for desmopressin, with approximately two-thirds of children becoming dry during active treatment and nearly one-half remaining dry after treatment completion (Glazener et al., 2005). In a large, multisite study of 2861 enuretic children (5 to 16 years of age), the overall success rate of bell-and-pad alarm therapy was 76%, irrespective of age (Apos et al., 2018). Enuresis alarms are activated when a sensor, placed in the undergarment or on a bed pad, detects moisture, with both types demonstrated to be equally effective (Butler and Robinson, 2002). The arousal device is usually an auditory alarm and/or a vibrating belt.

The family should be instructed that the child is in charge of the alarm. After the alarm goes off, only the child should turn off the alarm, get up, and finish voiding in the toilet. We often remind parents that at the initiation of therapy, the child may fail to awaken and that parents should wake the child when the alarm sounds. The child being fully awake and cognizant of what is happening is critical to the success of alarm therapy. The child should then return to the bedroom, change the bedding and underwear, replace the sensor, and reset the alarm before returning to sleep. A diary should be kept of wet and dry nights, with positive reinforcement given for dry nights and successful completion of the sequence of events. Approximately 30% of patients discontinue enuresis alarms for various reasons, including skin irritation, disturbance of other family members, and/or failure to wake the child (Schmitt, 1997). Adverse effects of alarms include alarm failure, false alarms, disruption of the lives of other family members, and lack of adherence because of difficulty using the alarm (Glazener et al., 2005).

Alarm treatment should be continued until the child has had a minimum of 14 consecutive dry nights (Nevéus et al., 2010). Children who do not continue to improve after 6 weeks of alarm training are unlikely to become completely dry with this technique (Taylor and Turner, 1975), and alternative interventions may be warranted. Therapy with the alarm can be reinitiated for relapse (more than two wet nights in 2 weeks). Children who relapse after discontinuation of the alarm usually can achieve a rapid secondary response because of preconditioning as a result of the first treatment program (Tuncel et al., 2008).

In a review of 1502 children in 15 randomized controlled trials comparing an enuresis alarm and desmopressin in managing children with MSE, the enuresis alarm outperformed desmopressin in achieving at least a partial response (>50% reduction in wet nights) in per-protocol analysis (odds ratio [OR] 1.53, 95% CI 1.05 to 2.23) but not in intention-to-treat analysis (OR 0.97, 95% CI 0.73 to 1.30) as the alarm was hampered by a high dropout rate (OR 2.20, 95% CI 3.41 to 4.29). In the intention-to-treat analysis, the results revealed that alarm and desmopressin therapy are comparable in efficacy with regard to achieving a greater than 50% reduction in baseline wet nights in enuretic children (Peng et al., 2018).

Pharmacotherapy

Desmopressin

Desmopressin (1-desamino-8-D-arginine vasopressin [DDAVP]) is a synthetic analogue of ADH released by the posterior pituitary gland that reduces urine production by increasing water reabsorption by the collecting tubules. DDAVP has been used to treat enuresis for the past 40 years. Desmopressin is fairly easy to administer, and its clinical effects appear immediately, with a serum half-life of approximately 2 to 3 hours when taken in oral form (the duration of pharmacodynamic action approximates the average duration of sleep for a child in the age range for elementary school). It is available in the United States in oral (crushable) tablets and in sublingual and intranasal spray formulations. The main safety issue is the risk for water intoxication with resultant hyponatremic seizures should the drug be taken with excessive fluids. This risk seems to be somewhat higher with the intranasal form, which has a prolonged half-life, and thus use of the spray is discouraged (Robson et al., 2007). Treatment should be interrupted during episodes of fluid and/or electrolyte imbalance (e.g., fevers, vomiting or diarrhea, vigorous exercise, or other conditions associated with increased water consumption).

The usual starting dose is 0.2 mg orally 1 hour before bedtime, and the drug can be titrated up incrementally by 0.2 mg to a maximum dose of 0.6 mg at bedtime. Children are instructed to void directly before going to bed. Fluid intake is reduced to a maximum of one 8-oz glass at the time of ingestion, with absolutely no more fluids until morning, decreasing the risk for significant hyponatremia to virtually zero (Glazener and Evans, 2002).

Desmopressin is most efficient in children with nocturnal polyuria (defined by the ICCS as nocturnal urine production >130% of expected bladder capacity for age) and normal bladder reservoir function (maximum voided volume >70% of expected bladder capacity for age) (Austin et al., 2014; Hunsballe et al., 1998; Rushton et al., 1996). There is a wide range of efficacy among studies, most likely because of heterogeneous patient populations (MSE vs. NMSE), differences in concomitant behavioral therapy recommendations, and differences in the dosage or formulation of DDAVP, without taking into account nocturnal urine volume. Overall, approximately 30% of patients achieve total dryness, and another 40% exhibit a significant decrease in nighttime wetting (Nevéus et al., 2010). However, the relapse rate after discontinuation is high (60% to 70%) (Wille, 1986). In a systematic review of 47 randomized trials (3448 children), researchers noted that compared with placebo, children treated with desmopressin were more likely to become dry and had a reduction in bedwetting by 1.34 nights per week (Glazener and Evans, 2002). In contrast with the enuresis alarm, however, treatment effects were not sustained after discontinuation of therapy, with a relapse rate of 65% versus 46% with DDAVP versus the alarm, respectively (Glazener and Evans, 2002).

The response to desmopressin should be assessed within 2 weeks (Schmitt, 1997). Treatment should be continued if there is a positive response (e.g., smaller wet patches, fewer wetting episodes). If enuresis improves or remits with desmopressin, the family and child can determine whether to use it every night or just for special occasions (e.g., sleepovers, summer camp). When DDAVP is administered daily, we generally give patients regular scheduled drug holidays of approximately 1 week every 3 to 6 months to assess whether the medication is still needed.

Tricyclic Antidepressants

TCAs have been demonstrated to decrease the amount of time spent in REM sleep, stimulate ADH secretion, and relax the detrusor muscle via weak anticholinergic properties. Its anti-enuretic effect has been theorized to be less likely because of its action at the kidney or bladder level and more likely a result of noradrenergic stimulation at the brainstem, specifically the locus coeruleus (Gepertz and Nevéus, 2004). Given the efficacy and safety of enuresis alarms and DDAVP, TCAs (e.g., imipramine, amitriptyline, and desipramine) are considered a third-line treatment for therapy-resistant MSE (Nevéus et al., 2010).

Level 1 evidence demonstrates that, compared with placebo, TCAs are more effective at reducing the number of wet nights and at achieving 14 consecutive dry nights (i.e., cure) but essentially become ineffective once treatment is discontinued.

In a recent systematic review, treatment with TCAs was associated with a reduction of approximately one wet night per week compared with placebo (Glazener and Evans, 2000). Approximately 20% of children became dry during therapy versus 5% with placebo. The rate of relapse was 96% after discontinuation of therapy. In an observational study of children who were refractory to first-line therapy, researchers found that approximately one-third of children became dry on monotherapy, one-third became dry after adding DDAVP, and the remaining one-third were nonresponders (Gepertz and Nevéus, 2004).

Although other TCAs are effective, imipramine is used most often in the treatment of enuresis. Imipramine is available in 10-, 25-, and 50-mg tablets. The initial dose is 10 to 25 mg 1 hour before bedtime; it may be increased by 25 mg if there is no response after 1 week (Schmitt, 1997). On average, the bedtime dose is 25 mg for children 5 to 8 years of age and 50 mg for older children. The dose should not exceed 50 mg in children between 6 and 12 years of age and 75 mg in children older than 12 years of age (Glazener and Evans, 2000).

The response to imipramine should be assessed after 1 month. If there is no improvement after 3 months, it should be discontinued as a gradual taper (as is done with other TCAs). As is the case with other pharmacotherapy for enuresis, we give patients a drug holiday every 3 to 6 months, gradually tapering the dose over a 2-week period (Gepertz and Nevéus, 2004).

Imiprimine is also an effective method of treating refractory daytime incontinence; in a pediatric population of 163 patients, 53% experienced complete treatment response as assessed by the Vancouver Symptom Score (VSS). Of the patients included in this retrospective study, only 13.3% experienced adverse effects (Franco et al., 2018).

Adverse effects of TCA therapy are relatively uncommon. Approximately 5% of children treated with TCAs develop neurologic symptoms, including nervousness, personality change, and disordered sleep. TCAs (as with other antidepressants) are required by the FDA to carry a black box warning regarding the possibility of increased suicidality, particularly in individuals with preexisting depressive symptoms. **The most serious adverse effects of TCAs involve the cardiovascular system: cardiac conduction disturbances and myocardial depression, particularly in cases of overdose** (Swanson et al., 1997). Before initiation of therapy with a TCA, a thorough cardiac history (e.g., palpitations, syncope) and family cardiac history (e.g., arrhythmias, sudden cardiac death) should be obtained with a baseline electrocardiogram to rule out a prolonged QT interval if history or physical examination raises suspicion. In an assessment of 64 trials in a Cochrane review covering the effects of tricyclic and related drugs in the treatment of enuresis, Caldwell et al. concluded that there was evidence for the effectiveness of TCAs in reducing the number of wet nights, but the effect was not sustained after treatment ceased. Combination of tricyclics and anticholinergics may also be more effective than monotherapy with tricyclics. Common side effects of dizziness, headache, mood changes, gastrointestinal discomfort, and neutropenia were observed (Caldwell et al., 2016).

Anticholinergics

Monotherapy with anticholinergic drugs, such as oxybutynin or tolterodine, has been demonstrated not to be effective as a first-line treatment for MSE (Lovering et al., 1988; Persson-Jünemann et al., 1993). Although evidence of efficacy from randomized trials is lacking, uncontrolled studies do show improvement in some children with NMSE, presumably because many of these children have a reduced functional bladder capacity (Caione et al., 1997; Nevéus, 2001). There is also some evidence that nocturnal detrusor overactivity (especially without nocturnal polyuria) plays a role in the pathogenesis of enuresis and therefore makes anticholinergics an attractive pharmacotherapeutic option (Nevéus, 2001).

Where anticholinergics clearly do have a role is combination therapy in the treatment of children who are refractory to DDAVP monotherapy. In the first randomized, placebo-controlled study of combination therapy with anticholinergics, Austin et al. (2008) studied 34 children with primary MSE who failed maximal-dose DDAVP monotherapy and assigned them, in a double-blind manner, to receive either extended-release tolterodine or placebo while all children continued to take DDAVP. Patients were reassessed after 1 month of therapy with a 1-week nocturnal record. They found a significant reduction in the mean number of wet nights in the combination therapy group compared with the placebo group. Furthermore, there was a 66% reduction in the risk for a wet episode compared with the placebo group. Montaldo et al. (2012) reported their results in 206 children with MSE refractory to DDAVP monotherapy who were randomized to 5 mg of oxybutynin or placebo and followed for 1 month. As predictive factors, bladder volume and wall thickness index, nocturnal polyuria, and voiding latency were considered. Corroborating the original study by Austin et al., the oxybutynin group showed a higher rate of full and partial responses than the placebo group. The responders to combined oxybutynin and desmopressin had a significantly lower bladder volume and wall thickness index than nonresponders.

Combination Therapy

The efficacy of the enuresis alarm plus desmopressin combination has been investigated in a number of studies (Bradbury, 1997; Fai-Ngo et al., 2005; Leebeek-Groenewegen et al., 2001; Sukhai et al., 1989).

Sukhai et al. (1989) reported a crossover trial of 28 children with primary MSE who were blindly allocated at random to a combination of enuresis alarm plus 20 mcg intranasal DDAVP or alarm plus placebo for 2 weeks. Patients received the other therapy after a 2-week treatment-free period. The combined treatment of desmopressin plus enuresis alarm resulted in significantly more dry nights per week during the 2 weeks of observation than the placebo plus the alarm. Although there was a significant difference between groups, the treatment period of 2 weeks was most likely too short for alarm therapy to contribute significantly to the outcome variable.

Bradbury compared the efficacy of enuresis alarm monotherapy to alarm treatment in combination with 40 mcg DDAVP nasal spray (Bradbury, 1997). At the end of the treatment period, children receiving combination therapy had more dry nights per week (mean: 6.1) than children using an alarm alone (mean: 4.8). In addition, more children achieved an initial success (4 weeks of dryness) after combination treatment (27 children [75%]) compared with alarm monotherapy (16 children [46%]). Interestingly, this improvement was most pronounced in children with severe wetting (>5 nights per week), family problems, or behavioral problems.

In a placebo-controlled study containing 93 patients with MSE, Leebeek-Groenewegen et al. (2001) compared 9 weeks of desmopressin plus alarm therapy with alarm monotherapy. They showed a significant decrease in the number of wet nights per week with combination therapy. After 6 months of follow-up, however, they reported that there was no significant difference between the two treatment groups regarding the efficacy and number of children who relapsed.

In a recent multicenter randomized controlled trial, Fai-Ngo et al. (2005) compared the efficacy of the enuresis alarm, oral DDAVP, and combined treatment in children with primary MSE. They assigned 105 children equally among groups to receive treatment for 12 weeks, and patients were then followed for 12 weeks after treatment. They found that the mean number of wet nights per week was significantly lower in the combination group than in the other groups at the conclusion of therapy. Desmopressin produced an immediate effect, but relapses were most common in the DDAVP monotherapy and combination therapy groups (60% and 40%, respectively). Alarms took several weeks to produce a benefit, but this was sustained on follow-up (20% relapse rate).

A reduction in the number of wet nights is consistently observed when using combination therapy of desmopressin and the moisture alarm compared with monotherapy. Enuresis relapse, however, is noted in some patients with long-term follow-up.

Alternative Therapies

Other drugs, including indomethacin, ephedrine, atropine, furosemide, and diclofenac, have been tried in the treatment of enuresis. A recent systematic review of randomized trials of drugs other than TCAs and DDAVP found that although indomethacin, diclofenac, and diazepam were better than placebo in reducing the number of wet nights, none of the drugs was better than desmopressin (Deshpande et al., 2012). A second recent review of complementary approaches such as hypnosis, psychotherapy, and acupuncture found limited evidence from small trials with methodologic limitations to support the use of such modalities for the treatment of enuresis (Huang et al., 2011).

Key Points: Enuresis

- The majority of children who present with enuresis have the nonmonosymptomatic form.
- The spontaneous resolution rate of enuresis is approximately 15% annually, such that only approximately 1% of teenagers will continue to be afflicted.
- Enuresis stems from a maturational delay in the ultimate development of bladder control, with three organ systems implicated in its pathogenesis: the bladder, the kidney, and the brain.
- The basic evaluation of the child with MSE includes history (including a voiding diary), physical examination, and urinalysis. The principal objective of the evaluation is to rule out BBD or enuresis as a manifestation of an underlying medical disease (e.g., posterior urethral valves, spinal dysraphism, diabetes mellitus) and to identify that the enuresis is truly monosymptomatic.
- Conventional therapies for enuresis include behavior modification, the

enuresis moisture alarm, and pharmacologic therapy (e.g., desmopressin, anticholinergics, imipramine).

Management of Defecation Disorders

Martin A. Koyle MD, FAAP, FACS, FRCSC, FRCS (Eng), Armando J. Lorenzo MD, MSc, FRCSC, FAAP, FACS

At first glance, a bowel management chapter may appear out of place in a urology textbook. However, clinical experience has called attention to a deep interrelation between urinary and bowel function. The past decade has witnessed a greater understanding of the pelvic floor working as a functional unit that blends artificial barriers sets by specialty training. The lower gastrointestinal and genitourinary tract share embryologic origin, anatomic location, innervation (motor and sensory), volitional control with normal development, and sphincteric mechanisms. On clinical grounds this is evidenced during careful history and exam, with frequent dual dysfunction in neurologic conditions (neuropathic bladder and bowel in disease processes of the lower spinal cord), bladder capacity compromise resulting from a distended rectum (Fig. 36.1), and dysfunctional elimination rarely affecting only one system (instead often seeing concurrent urinary and bowel symptomatology in affected children). Thus understanding of urinary tract dysfunction is incomplete without considering and addressing all aspects of elimination, including defecation.

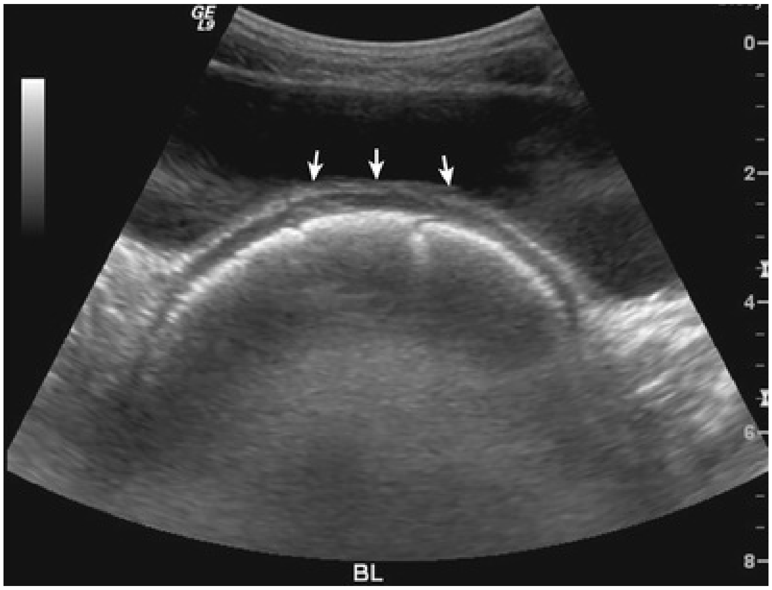

FIG. 36.1 Pelvic ultrasound demonstrates anterior displacement of the bladder wall with decrease in functional bladder capacity resulting from a large amount of fecal material in the rectum *(arrows).*

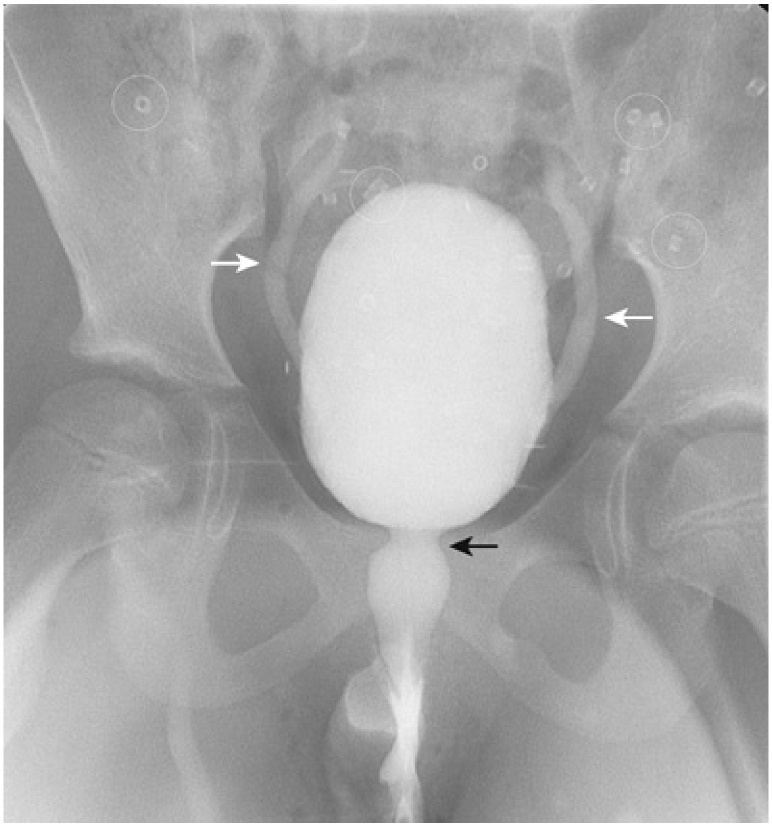
Anomalies of the bowel and urinary tract frequently coexist, whether functional, anatomic, and/or neuropathic. Constipation and rectal distention may adversely affect bladder function (Burgers et al., 2010), leading to low functional bladder capacity, incontinence, predisposition to urinary tract infections, and triggering or exacerbating vesicoureteral reflux (eFig. 36.2; Loening-Baucke, 1997; Yazbeck et al., 1987). In addition, constipation is a common side effect of medications employed to deal with lower urinary tract symptoms (anticholinergics). Because of this common association, pediatric urologists have become comfortable with assessing and managing bowel problems in the everyday care of children and adolescents with genitourinary complaints. Contemporary management of children with dysfunctional elimination calls for routine simultaneous assessment of the gastrointestinal and genitourinary tracts. Good understanding of medical and surgical options is also warranted because it is often the urologist who is in a position to manage urinary and fecal problems synchronously (Burgers et al., 2013).



EFIG. 36.2 Voiding cystourethrogram in a patient with dysfunctional elimination and recurrent episode of pyelonephritis. Note the presence of bilateral vesicoureteral reflux *(white arrows)* and “spinning top” deformity of the bladder neck during voiding *(black arrow).* Patient previously underwent a motility study because of persistent constipation despite stool softeners (note encircled radio-opaque markers).

Key Points

- The bladder is not an isolated organ. On the contrary, it works in a close functional and anatomic relationship with surrounding structures, including the lower gastrointestinal tract.
- Constipation is common yet hard to ascertain just by asking children or parents.
- Neurologic problems can affect urinary and bowel systems, as seen in patients with neuropathic bladder dysfunction.
- Medications commonly employed for bladder management (most notably, anticholinergics) have an adverse impact on bowel function.

- Pediatric urologists are in a privileged position to effectively address bowel function and positively affect the child's well-being and quality of life.

Epidemiology and Classification of Disorders of Defecation

Defecation disorders are common throughout life, including childhood. **In children, these are most often manifested as infrequent bowel movements without a specific underlying organic cause, thus labeled as "functional" constipation.** Reported prevalence in the pediatric population ranges between 0.7% and 29.6%, with no significant difference in rates for boys and girls (van den Berg et al., 2006). It is a frequent reason for evaluation by family medicine health care providers, pediatricians, pediatric gastroenterologists, pediatric surgeons, and, because of associated lower urinary tract symptoms, pediatric urologists. Common presenting symptomatology includes infrequent defecation, abdominal bloating or distention, painful bowel movements, abdominal pain, and fecal incontinence (Nurko and Scott, 2011). Although there are multiple potential causes (Table 36.1), most children have a negative assessment for associated conditions. Functional constipation is, in essence, a diagnosis of exclusion, defined as a defecation disorder not associated with congenital or acquired abnormalities or specific medications. Nevertheless, concerns over an organic cause often trigger an overtly extensive, occasionally invasive, and expensive workup.

TABLE 36.1

Differential Diagnosis of Chronic Constipation

Idiopathic or functional
Behavioral: Dysfunctional elimination due to defecation avoidance, intellectual disability, psychological problems, adverse life event
Poor dietary habits: Low fluid and fiber intake
Structural defects: Anorectal malformation, anal stenosis, Hirschsprung disease, extrinsic compression by pelvic mass, deficient abdominal musculature (most notably, prune-belly syndrome)
Neurologic disorders: Isolated to spinal cord (myelomeningocele, tethered cord, trauma, transverse myelitis, postsurgical, tumors), cerebral palsy, muscular dystrophy, neurodegenerative disorders

Endocrine disorders associated with chronic dehydration (such as diabetes insipidus) and electrolyte disorders (most notably hypercalcemia and hypokalemia), hypothyroidism, hypervitaminosis D

Cystic fibrosis

Celiac disease

Connective tissue disorders (such as Ehlers-Danlos syndrome)

Food intolerance (cow's milk) and other food allergies

Medications: Anticholinergics, opioid analgesics, anticonvulsants, antidepressants and antipsychotics, iron and calcium supplements, antispasmodics, diuretics

Other bowel motility disorders: Colonic dysmotility, chronic pseudo-obstruction

Of all the functional gastrointestinal disorders of childhood (e.g., irritable bowel syndrome, functional bloating, functional constipation, and functional diarrhea [Longstreth et al., 2006]), constipation is the one most frequently encountered by pediatric urologists. It demands expertise in management along with ruling out other pathologies that require specialized assessment and treatment. Thus pediatric health care providers in modern specialized centers should be comfortable with addressing constipation.

Normal Versus Abnormal Bowel Function

The definition of normal bowel function has to be framed within the context of age, developmental issues, and cultural expectations. Although seemingly simple, normal bowel function is often difficult to define and ascertain. Despite expected variation in toilet-training age, children are expected to begin experimentation at age 2 and completely gain control of the defecation process by age 3 (Wald et al., 2009). Past this age, bowel movement normal frequency varies from three stools per week to three stools per day. The majority of children 5 to 8 years of age have a bowel movement daily or every other day, without straining or withholding (Fontana et al., 1989; Wald et al., 2009). Unfortunately, children with irregular, incomplete, and/or infrequent defecation may not report symptoms, and parents are often surprisingly unaware of their child's bowel routine. To aid with assessment, the presence of constipation should be ascertained with standardized diagnostic tools, such as the Rome IV criteria (Table 36.2; Hyman et al., 2006; Rasquin et al., 2006; Zeevenhooven et al., 2017). These criteria take into account three important considerations:

absence of an organic underlying cause, developmental stage (toilet trained vs. not toilet trained), and duration of symptoms.

TABLE 36.2

Rome IV Diagnostic Criteria for Functional Constipation

Must include 1 month of at least 2 of the following in infants up to 4 years of age:

1. 2 or fewer defecations per week
2. History of excessive stool retention
3. History of painful or hard bowel movements
4. History of large-diameter stools
5. Presence of a large fecal mass in the rectum

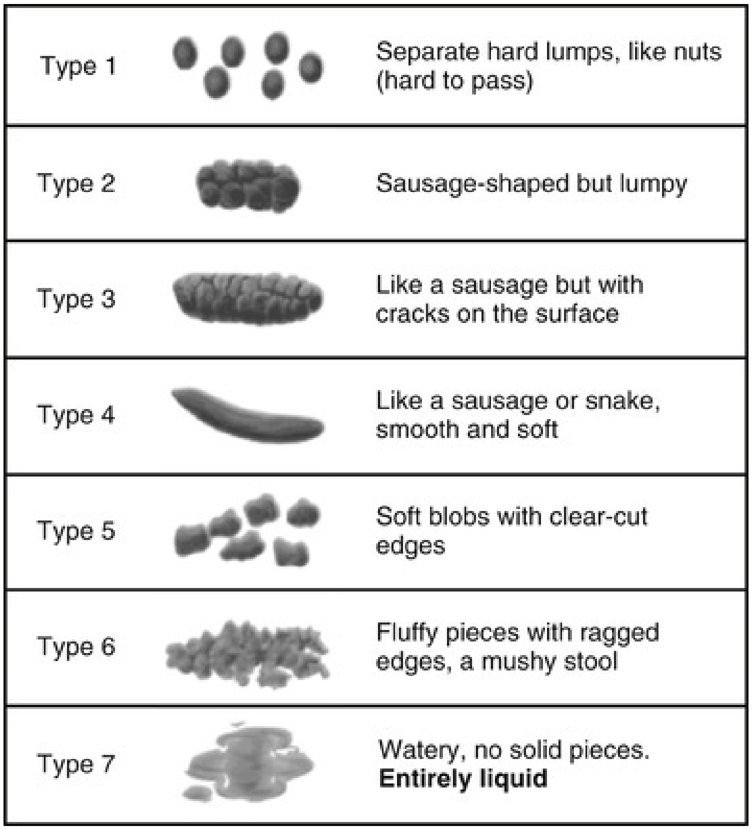
In toilet-trained children, the following *additional* criteria may be used:

6. At least 1 episode/week of incontinence after the acquisition of toileting skills
7. History of large-diameter stools that may obstruct the toilet

From Benninga MA, Faure C, Hyman PE, et al: Childhood functional gastrointestinal disorders: neonate/toddler. *Gastroenterology* 2016 (online journal): https://doi.org/10.1053/j.gastro.2016.02.016.

Evaluation of Abnormalities of Defecation

A good history and physical examination are the cornerstone of evaluation and may suffice for diagnosis and initial management of most children. A detailed previous medical history is clearly relevant. Critical information to be actively gathered includes age of onset of symptoms, failure to toilet train within an age-appropriate and developmental timeframe, frequency of bowel movements, stool consistency (assessed by appearance, and preferably recorded with existing stool scales, such as the Bristol stool form scale [Lewis and Heaton, 1997; Longstreth et al., 2006] as shown in Fig. 36.3 or modifications [Chumpitazi et al., 2010; Lane et al., 2011]), pain with defecation, bleeding per rectum, presence and characteristics of associated abdominal pain, fecal incontinence, holding behaviors, dietary history, changes in appetite, nausea or vomiting, weight loss, growth pattern (including height and weight), developmental delay, and failure to thrive. **The age of onset of symptoms is one of the easiest and most important pieces of information to obtain,** because it can be an important indicator for underlying pathology (Table 36.3). A detailed previous surgical history is also of great value, and attention should be paid to prior correction of anorectal malformations, resection of sacrococcygeal teratomas or other pelvic tumors, closure of spinal dysraphism, spinal cord untethering, and genitourinary reconstruction for conditions such as prune-belly syndrome.



Type 1
Separate hard lumps, like nuts (hard to pass)
Type 2
Sausage-shaped but lumpy
Type 3
Like a sausage but with cracks on the surface
Type 4
Like a sausage or snake, smooth and soft
Type 5
Soft blobs with clear-cut edges
Type 6
Fluffy pieces with ragged edges, a mushy stool
Type 7
Watery, no solid pieces. **Entirely liquid**

FIG. 36.3 The Bristol stool form scale.

TABLE 36.3

Warning Signs and Symptoms

Constipation, fecal impaction that predates bowel training, particularly in the first year of life[a]

Chronic or recurrent respiratory problems[b]

Need for medications or rectal stimulation in the first year of life, particularly breastfed infants

Bloody stools

Alternating constipation and diarrhea

Severe or constant abdominal pain

History of bowel obstruction
Associated weight loss, growth retardation, failure to thrive[c]
Hypotonia, developmental delay[d]
Decreased appetite, early satiety
Bilious vomiting
Ribbon-like stools
Fecal and urinary incontinence beyond age of toilet training
Associated neurologic symptoms, particularly in the lower extremities (weakness, gait abnormalities, muscle atrophy, sensory abnormalities)
Lower back abnormalities (sacral dimple, lipoma, hair tuft, gluteal cleft deviation)
Explosive stool and air from rectum after stimulation (digital, suppository) or after rectal exam

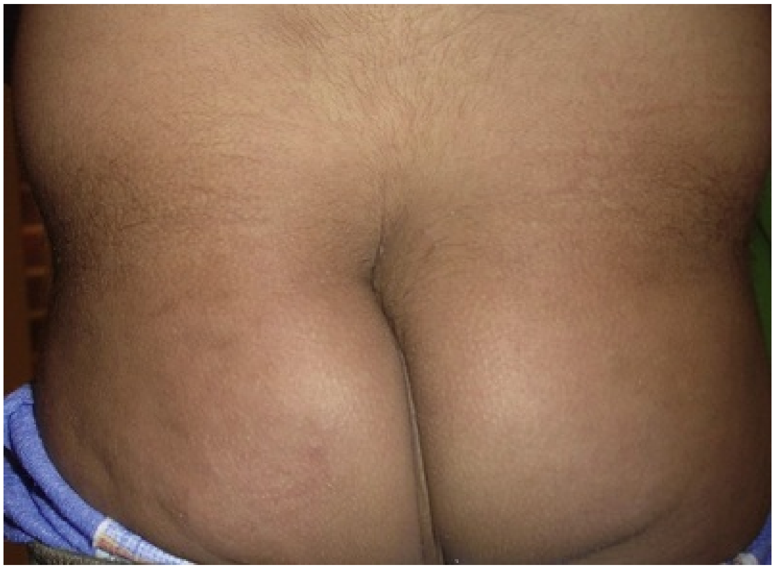
[a] Onset of symptoms in infants <1 month old or delayed passage of meconium by 48 hours in a term neonate should raise suspicion for an organic condition, specifically Hirschsprung disease (Ghosh and Griffiths, 1998); a consideration should be given to ruling out the diagnosis with a rectal biopsy.

[b] Suspect cystic fibrosis.

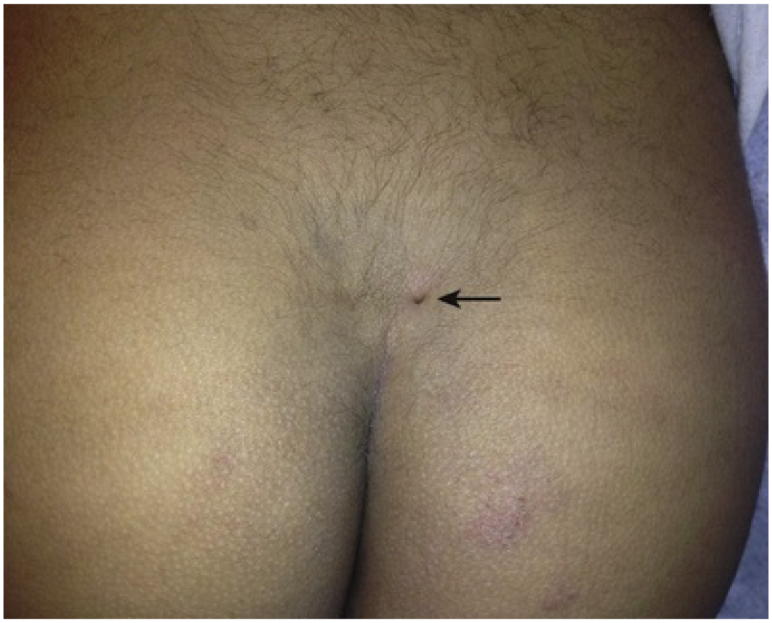
[c] Suspect celiac disease, hypothyroidism, and Hirschsprung disease.

[d] Associated with hypothyroidism and trisomy 21.

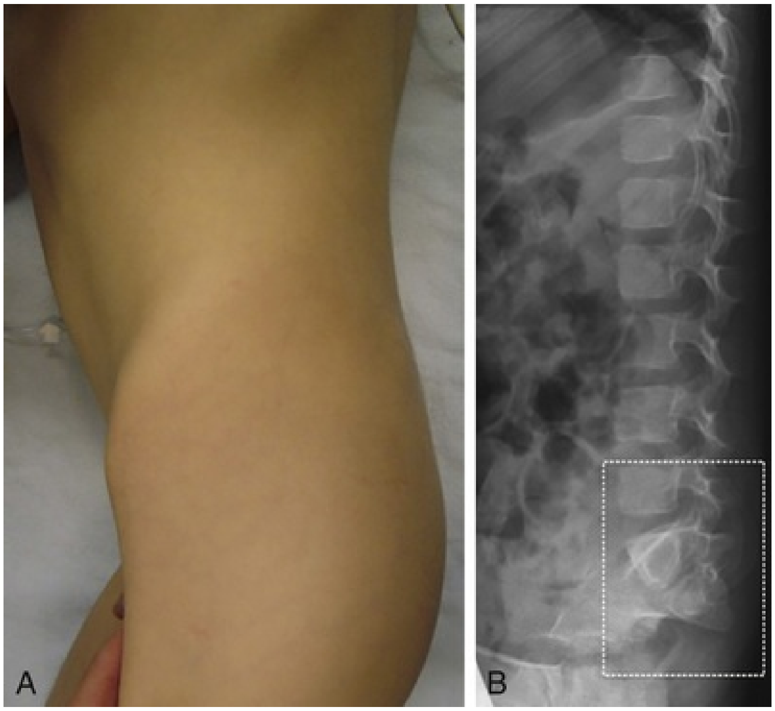
Critical components of physical exam include appearance of the perianal region and perineum, abdominal exam (including presence of palpable masses, muscle tone, distention, pain on palpation), presence of a cremasteric and anal reflex, gluteal and sacral region assessment (for hair tufts, deviated gluteal cleft [eFig. 36.4], sacral dimples, [eFig. 36.5], flat buttocks [eFig. 36.6]), and lower extremity exam (weakness, coordination, muscle atrophy, decreased muscle strength, abnormal deep tendon reflexes, gait abnormalities). Although often an obvious diagnosis on physical exam, the presence of cryptorchidism (or prior bilateral orchidopexies for intra-abdominal gonads), lax abdominal wall, and lower urinary tract problems should raise concern for prune-belly syndrome and have appropriate assessment to consider abdominoplasty as a means to address difficulty generating increased intra-abdominal pressure for defecation.



EFIG. 36.4 Deviated gluteal cleft in a child with neuropathic bladder and bowel dysfunction secondary to cord tethering and occult dysraphism.



EFIG. 36.5 Sacral dimple *(arrow).*



EFIG. 36.6 Sacral agenesis. (A) Findings on physical exam, including a “flat” appearance of the buttocks, associated with neuropathic bladder and bowel. (B) Lateral view lumbosacral radiograph with bony defects of the lower spine consistent with sacral agenesis (or caudal regression syndrome).

Physical exam should also include weight and height (parameters graphed against normal growth curves) and inspection of the anal region (anal position, stool present around the anus or on the underwear, signs of trauma, anal fissures, sensation). Although potentially considered to be an integral part of a complete physical exam, **digital rectal examination should not routinely be performed in children**. It is reserved for difficult-to-treat cases and should be conducted by health care professionals comfortable with interpreting features of anorectal anatomic abnormalities (Mugie et al., 2011), to specifically evaluate for anal stenosis, a large fecal mass, or an empty rectum. **Extreme fear during anal inspection, fissures, or signs of trauma should raise suspicion for sexual abuse.**

Assessment of patients with functional constipation should be fairly normal. Expected findings are those of a well-appearing child, with weight and height within normal limits, normal appearance of anus and surrounding area, a soft abdomen (occasionally distended or with a palpable fecal mass in the left lower abdominal quadrant), normal appearance of the skin and anatomic structures of lumbosacral/gluteal regions, normal gait, tone strength, and lower limb reflexes.

In addition, these patients should not have clinical manifestations until at least a few months of life, having a history of normal passage of meconium (within the first 24 to 48 hours after birth). Presentation sometimes coincides or worsens with precipitating factors, such as change in diet (e.g., transitioning out of breastfeeding), new medications (e.g., anticholinergics for management of urinary frequency), or psychosocial stressors (i.e., moving, starting, or changing school, parents separating, new sibling, major illness in family, travel).

Aside from abnormalities on physical exam, based on history and ancillary tests, selected children need a focused workup for organic conditions that manifest themselves or are associated with elimination problems. These include cystic fibrosis, hypothyroidism, celiac disease, dietary allergies, Hirschsprung disease or colonic aganglionosis, anal stenosis, and trisomy 21. Laboratory evaluation in refractory cases or those with associated worrisome findings include celiac screening and thyroid function tests (TSH, T_4). In older children and teenagers, other conditions should be added to the differential, such as mental health issues (depression), eating disorders, sexual abuse, and irritable bowel syndrome (IBS) (Longstreth et al., 2006). IBS, a functional bowel disorder, is characterized by abdominal pain associated with defecation or a change in bowel habits. Diagnosis depends on key temporal relationships: recurrent abdominal discomfort at least 3 days per month in the past 3 months associated with improvement with defecation and onset or worsening with a change in frequency or stool form (appearance).

Imaging Studies

Although of modest clinical value, along with exposure to a very low dose of radiation, abdominal radiographs are commonly employed in the diagnosis and management of defecation disorders, particularly constipation. The sensitivity and specificity of abdominal radiography in diagnosing childhood constipation is far from optimal, ranging between 60% and 80% and 40% and 90%, respectively (Mugie et al., 2011; Reuchlin-Vroklage et al., 2005). The test's interpretation can be subjective, and findings can be affected by timing since the child's last evacuation. Nevertheless, scales have been devised to help standardize evaluations, based on estimated bowel dilation, as well as the pattern, amount, and distribution of feces in the colon, which provides scores that can be useful for diagnosis, monitoring, and research purposes (Barr et al., 1979; Blethyn et al., 1995; Leech et al., 1999; van den Bosch et al., 2006). Proponents in favor of routine radiologic assessment argue that the study can clearly demonstrate the amount of fecal loading, delineate stool distribution throughout the colon and rectum (Fig. 36.7), as well as help ascertain for the presence of fecal impaction (which has important therapeutic implications) (Fig. 36.8). In addition, it may also reveal associated pathologies, such as bony abnormalities indicative of occult spinal dysraphism or sacral agenesis (eFig. 36.9), and help provide a visual aid for family and patient recognition of stool retention despite a history of regular defecation. In turn, this can be useful to maximize adherence to treatment in cases in which there is disagreement or disbelief with the presence of constipation (particularly if consulting solely for lower urinary tract symptoms or urinary tract infections). Serial exams may also provide an objective way to monitor response to disimpaction and/or maintenance treatment (taking the *ALARA*, *A*s *L*ow *A*s *R*easonably *A*chievable, radiation exposure principle into account), although many would contend that considering symptomatic improvement alone is sufficient. In some circumstances, the study can be replaced or enhanced by conducting ultrasound evaluation of the lower abdomen and pelvis, assessing fecal loading behind the bladder as an alternative or adjunct marker for constipation (Joensson et al., 2008; Klijn et al., 2004; Fig. 36.10). Ultimately, **if constipation and fecal impaction or loading are obvious on history and physical examination, management based on clinical grounds without imaging studies is reasonable and recommended in routine practice** (Tabbers et al., 2014).

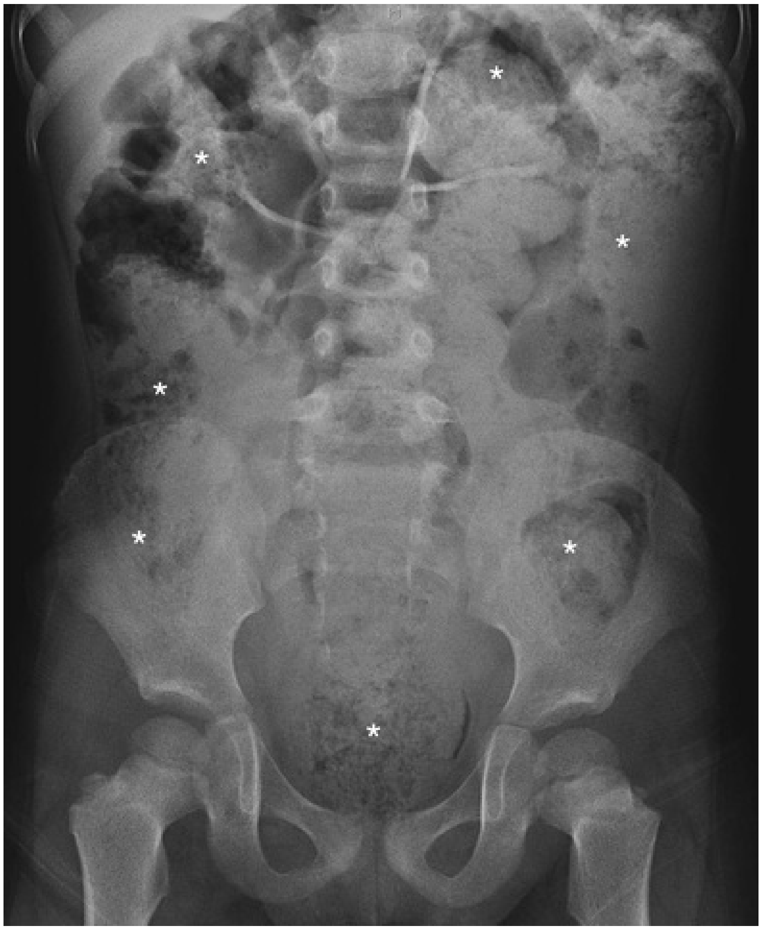


FIG. 36.7 Abdominal radiograph demonstrating fecal loading throughout the colon (*) in a child abdominal distention, encopresis, and urinary frequency.

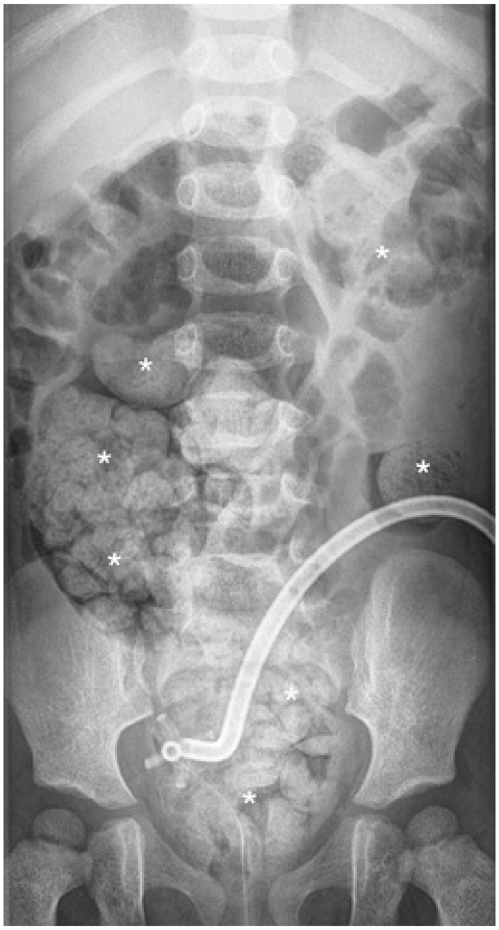

FIG. 36.8 Abdominal x-ray with evidence of fecal impaction in a child who presented with acute urinary retention (note placement of suprapubic tube for bladder management).

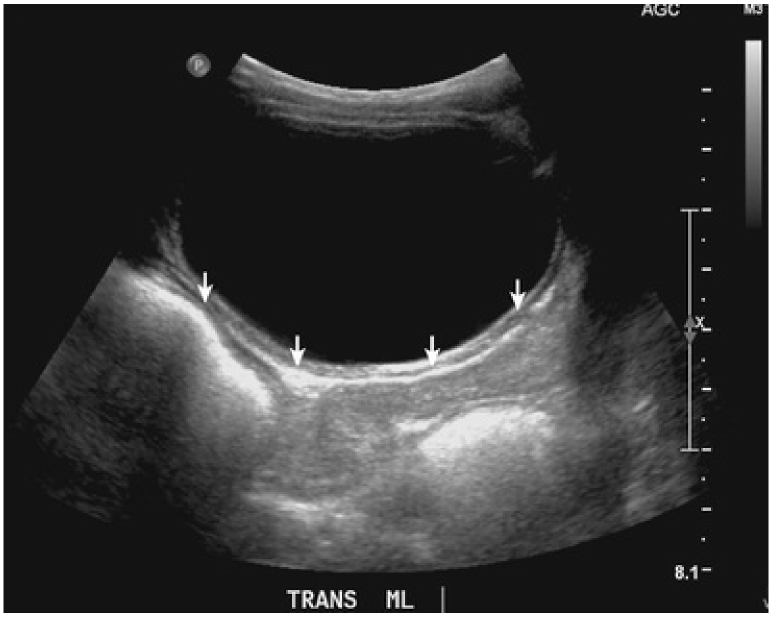

FIG. 36.10 Assessment of fecal load in rectum during pelvic ultrasound. Stool is seen behind the bladder *(arrows).* Note bladder distention due to incomplete emptying and infrequent voiding because of toilet avoidance secondary to pain with defecation.

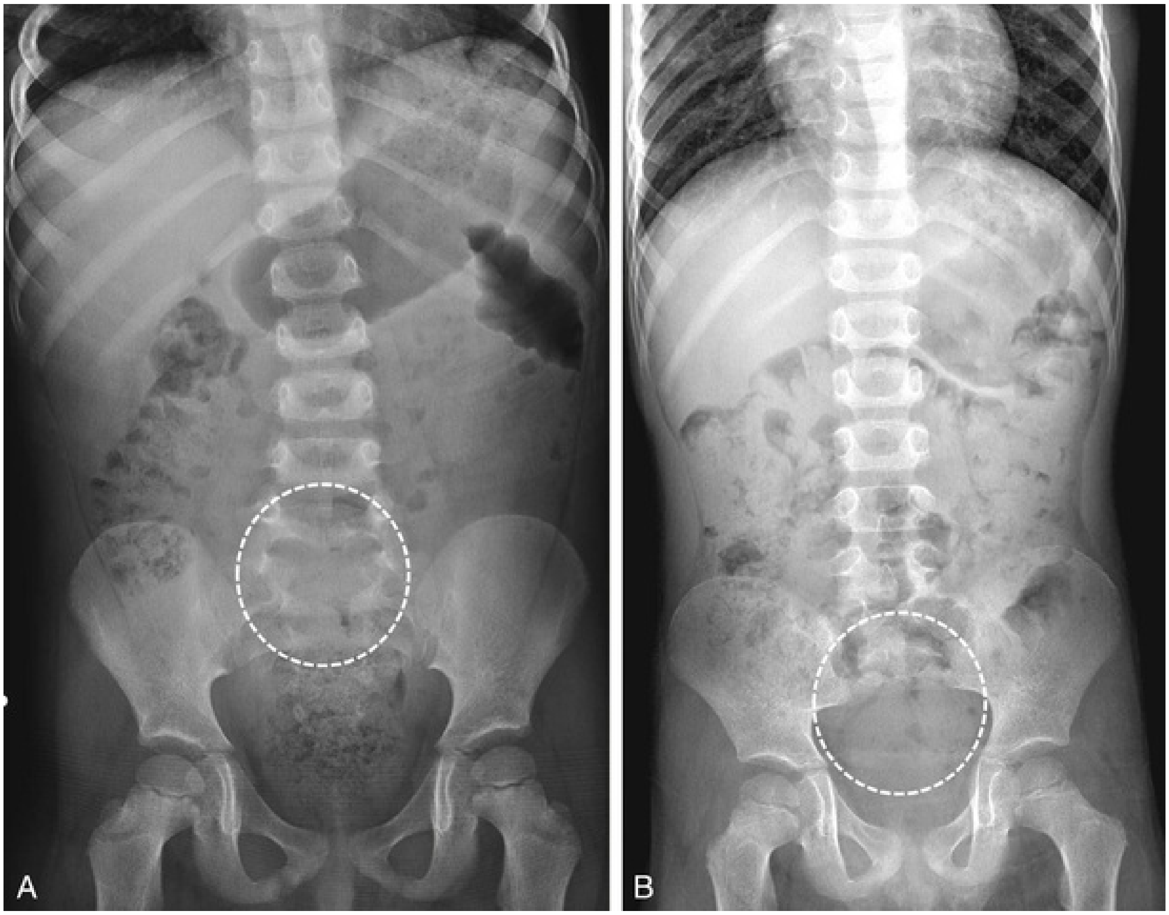

EFIG. 36.9 Bony abnormalities detected on abdominal x-ray during assessment of difficult-to-treat constipation. (A) Lumbar bony defects consistent with occult spinal dysraphism. (B) Absent sacrum, suggestive of sacral agenesis.

Colonic transit time studies, which evaluate the progression of radio-opaque markers along the gastrointestinal tract on serial radiographs, are not recommended for routine diagnosis of functional constipation. However, in difficult to treat or unresponsive cases this study may have some value: a normal evaluation in the setting of fecal incontinence would suggest either a nonretentive defecation disorder or an unreliable medical history. Additional studies are selectively obtained based on suspicion for an underlying condition. A contrast enema series can be of value in the evaluation of children with characteristics suggestive of Hirschsprung disease (Langer, 2013; Reid et al., 2000; Fig. 36.11) and repaired congenital anatomic abnormalities (i.e., anorectal malformation). Concern for a neuropathic process and/or lower spine stigmata should be evaluated with a spine ultrasound (if detected before calcification of the vertebral bodies in the first 3 to 6 months of life, eFig. 36.12) or a lumbosacral MRI in older children (eFig. 36.13). Suspicion for sacral agenesis should be further assessed with a lateral view lower spine/pelvis radiograph (see Fig. 36.6).

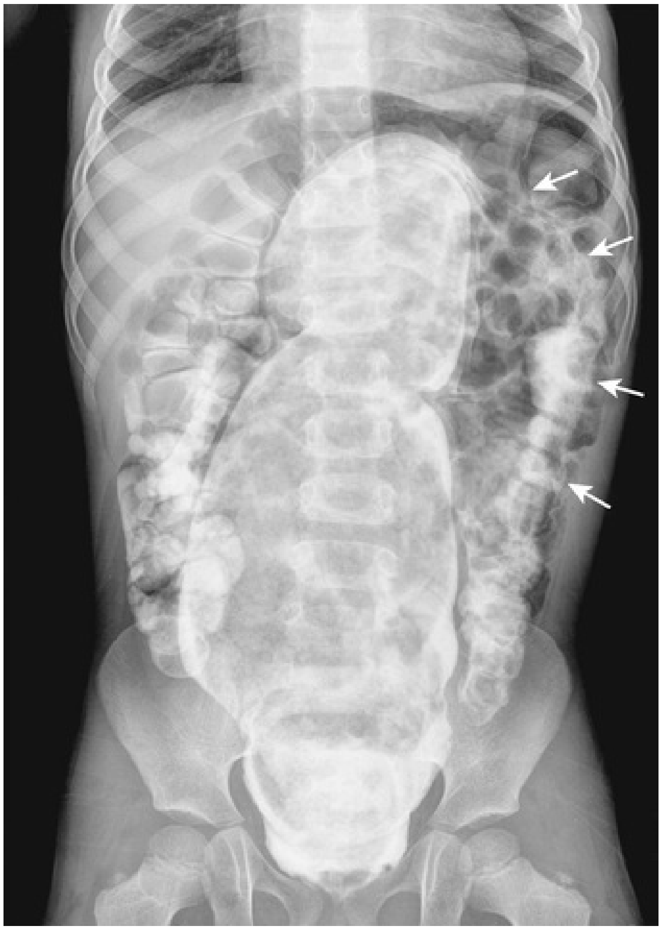

FIG. 36.11 Soluble contrast enema for evaluation of child with defecation problems since birth. Findings suggestive of Hirschsprung disease, including massively distended colon and rectum than can progress toward more normal-appearing large bowel *(arrows).* This child was subsequently assessed with a rectal biopsy to confirm the diagnosis.

EFIG. 36.13 MRI of lumbosacral region in a child with abnormal lower back exam during initial assessment of constipation and urinary frequency.

Note presence of lipoma extending into the spinal canal *(arrows).*

If Hirschsprung disease or colon aganglionosis is suspected, a deep rectal suction biopsy (including submucosal) should be obtained (Langer, 2013), favoring a transanal approach and aiming at a location 2 to 3 cm from the dentate line. Diagnosis is supported by absence of ganglion cells, hypertrophied nerve fibers, and increase in acetylcholinesterase activity in the lamina propria and muscularis mucosa. Anorectal manometry is useful only in very selected cases (Noviello et al., 2009), such as suspected Hirschsprung disease and internal sphincter achalasia. In these conditions, the rectoanal relaxation reflex is absent. Nevertheless, in most patients suspected of having functional constipation, manometry adds little to the diagnosis or therapeutic strategy (van Ginkel et al., 2001).

Key Points

- The Rome IV criteria are recommended for diagnosis of functional constipation in children.
- The diagnosis of functional constipation should be based on a good medical history and physical examination.
- The presence of alarm signs or symptoms or intractable constipation should trigger a focused assessment to diagnose underlying medical conditions.
- Routine use of abdominal radiographs is of limited value and should be reserved for selected cases, such as suspected fecal impaction and difficult or unreliable history and physical examination.

Management

As is the case with many other conditions, careful thought and consideration must be first given to more conservative, nonoperative management alternatives (see management algorithm, Fig. 36.14). A medical plan, consisting of behavioral interventions, dietary changes, stool softeners and laxatives, and judicious use of retrograde enemas is often sufficient to manage most patients with chronic constipation. In addition, education about defecation and demystification of toilet training (in children with a developmental age of at least 4 years) are crucial yet often overlooked components of successful management (van der Plas et al., 1997). Clearly, whether a functional problem or associated with an organic underpinning, especially considering the spectrum of associated urologic disorders, an individualized approach to each patient is preferred.

FIG. 36.14 Management algorithm for childhood defecation disorders seen in a pediatric urology practice. Lack of improvement or intractable constipation should be diagnosed based on worsening or absence of suboptimal response to adequate medical treatment for at least 3 months.

Treatment of constipation is often started within the context of lower urinary tract symptoms. The association between the two has gained acceptance, and simultaneous assessment is part of the comprehensive evaluation offered in many pediatric urology practices, often run by nurse practitioners and other health care providers. The concept's popularity is based on data from a landmark study by Loening-Baucke, who reported on 234 consecutive patients with constipation and encopresis and associated urinary incontinence and urinary tract infections. Successful relief of constipation in 52% was associated with resolution of daytime urinary incontinence in 89%, of nocturnal enuresis in 63%, and a resolution of infections (Loening-Baucke, 1997). Although backed up by experience and other subsequent case series, demonstrating improvement in incontinence episodes, voided volume, and postvoid residuals (Erickson et al., 2003), the value of universal use of laxatives in children requiring treatment of overactive bladder symptoms has been called into question (Bush et al., 2013). Nevertheless, if constipation is suspected, treatment should be recommended, as highlighted in the 2013 report from the Standardization Committee of the International Children's Continence Society (Burgers et al., 2013).

Nonpharmacologic Interventions

If screening and imaging studies are negative, thus restricting the diagnosis to a functional elimination problem and/or slow colonic transit time, medical management follows a stepwise process that begins with medical therapy coupled with behavioral modifications: adequate fluid and fiber intake, regular defecation, scheduled post-meal defecation attempts to take advantage of an increase in colon motility in response to gastric distention and digestive process (so-called gastrocolic reflex), relaxation techniques, and proper positioning on the toilet (with good foot support and forward leaning to flex thighs closer to the abdomen and better generate an increase in abdominal pressure). Obviously, in cases in which an underlying organic cause is suspected, specific therapy should be sought after a directed workup.

Behavioral and dietary recommendations are often implemented first and may suffice as a stand-alone strategy or as an adjunct to medical or surgical interventions. The impact of these is difficult to measure because of wide differences in employed protocols, a high placebo response rate in some subgroups (Bush et al., 2013), and attrition (patient lost for follow-up). Nevertheless, lack of benefit is often based on limited data, families commonly attempt therapeutic trials without recommendation or supervision by a health care provider, parents often favor nonpharmacologic strategies despite unproven benefit, and side effects are often mild or negligible. Thus the expectation is that early on, children will be asked to implement generous fluid intake (in accordance with expectations for children with lower urinary tract symptoms), optimize diet (including liberal fiber intake in the form of fruits and vegetables), establish a bowel routine taking advantage of the gastrocolic reflex, ensure active lifestyle (promoting physical activity and avoid sedentary tendencies), and consider the use of pre- and/or probiotics (Chmielewska and Szajewska, 2010; Korterink et al., 2013), additional fiber intake (Castillejo et al., 2006;

Chmielewska et al., 2011; Loening-Baucke et al., 2004; Staiano et al., 2000), or biofeedback (van der Plas et al., 1996a,b). Unfortunately, any positive effect on functional constipation is hard to defend based on high-quality data (Tabbers et al., 2011), and treatment algorithms tend to be based on opinion rather than evidence (Pijpers et al., 2010).

The chronic nature of defecation disorders, in combination with fears of adverse effects or irreversible reliance on daily medication use, contributes to parents seeking some form of alternative treatment in approximately 40% of children with functional constipation (Vlieger et al., 2008). Many of these, aside from having unknown effectiveness, can be associated with important complications or discomfort (hypnotherapy, acupuncture, homeopathy, and osteopathic or chiropractic musculoskeletal manipulations, transcutaneous nerve stimulation) and should be avoided or only employed under a research setting until backed up by well-designed studies. In particular, phytotherapy (favored by parents who equate "natural" with safety) can elicit severe adverse reactions because of contamination, inability to quantify active compounds, unknown adulteration, or direct toxic effects.

Disimpaction and Large Bowel and Rectum Washout

Decreasing fecal load in the large intestine and rectal vault is the first step toward establishing an optimal medical regimen. Impaction is defined as the presence of a hard mass in the lower abdomen and/or left lower quadrant, or a dilated rectum filled with a large amount of stool as determined by rectal examination, pelvic ultrasound, or abdominal radiography, irrespective of the ability to produce bowel movements. **The child may be able to pass some stool without effectively emptying, and on occasion may have loose bowel movements that can be paradoxically (and erroneously) labeled or treated as diarrhea.** Approximately 30% of children with long-lasting functional constipation have fecal impaction, frequently associated with stool incontinence (Mugie et al., 2011; Nurko and Scott, 2011). The presence of fecal impaction demands attention before initiation of maintenance medical management; otherwise treatment will fail or paradoxically worsen gastrointestinal symptoms.

Disimpaction and bowel washout, as the names imply, attempt to address the problem in a relatively short period of time, accepting the need for enemas or stimulants, and tolerating temporary worsening of fecal incontinence, abdominal distention, and discomfort. In stark contrast to maintenance therapy, enemas and suppositories are acceptable as routine interventions during this period and may facilitate evacuation of a large/hard fecal load in the rectum. Although subject to variability based on the amount of fecal material, distribution within the colon, child's age, tolerance for medication administration per anus, provider experience and cultural barriers, common programs include “high-dose” polyethylene glycol (or PEG, 1–1.5 g/kg/day for 3–6 days) with or without sodium chloride, sodium phosphate, or mineral oil enemas (daily for 3–6 days) (Tabbers et al., 2014). The ultimate goal is to produce soft, watery bowel movements with correction of abdominal distention, palpable fecal mass on abdominal or rectal exam, and clearance of fecal load as determined by abdominal plain film or pelvic ultrasound.

In rare circumstances clearance can only be achieved with more aggressive medication administration, conducted during admission to the hospital, and aided by nasogastric tube delivery and intravenous fluids to prevent dehydration (similar to local protocols for preoperative bowel preparation). If failed, not tolerated, or associated with severe pelvic pain because of difficulty in passing a hard, large rectal fecaloma, digital disimpaction under anesthesia may be required. Subsequent outpatient management requires regular (often daily) visits and consists of monitoring response while modifying the volume and content of the retrograde enemas to suit the individual needs of each patient. Normal saline is commonly used as the solution for enemas, with additives employed based on preference and familiarity with use (glycerin, soap, or phosphate). Commercial sodium phosphate formulations (such as Fleet enema) can be added in difficult cases but should be employed with caution in children with renal impairment. Dosage is adjusted by age: 30 mL for children younger than 4 years old, 60 mL for children 4 to 10 years old, and 120 mL for children older than 10 years of age. The total volume of the enema must be tailored to effect, with constipated patients often requiring up to 500 to 1000 mL. Management is considered successful when the underwear remains clean for 24 hours.

Maintenance Therapy

Before beginning any maintenance protocol, the provider should verify that the rectosigmoid is not impacted again, despite what was thought to be an adequate washout. Failure to do so means management is bound to fail, paradoxically leading to overflow fecal incontinence or triggering pain and cramping with oral medications. In contrast to management of fecal impaction, routine rectal administration of medications is avoided as first-line maintenance therapy. Although tolerated by some children, the use of enemas over optimal oral medical therapy does not appear to provide added benefit (Bongers et al., 2009). There is, however, limited place for routine use of enemas, suppositories, or rectal stimulation in selected, severe, difficult-to-treat cases.

Osmotic laxatives, such as lactulose, milk of magnesia, and polyethylene glycol (PEG), are usually sold as solutions or powders to be dissolved in water, thus making them relatively easy to administer to children and thus preferred agents. They act as poorly absorbed hyperosmolar molecules, increasing stool water content (making feces softer and easier to pass), and increasing colonic peristalsis. Stimulant laxatives (sodium picosulfate, senna, and bisacodyl), which act directly on the intestinal mucosa, increase water and electrolyte secretion and are often reserved for second-line or adjuvant (intermittent) protocols, employed only in selected (otherwise refractory) circumstances.

With the introduction of PEG into routine clinical practice, tolerance of medical management has improved and is currently the preferred agent in many centers. PEG is better tolerated and easier to administer than alternative medications such as lactulose, mineral oil, and milk of magnesia (magnesium hydroxide) (Gordon et al., 2012, 2013). Maintenance PEG dose is 0.2 to 0.8 g/kg/day, further adjusted based on clinical response, and given with fluids either once or twice a day. It is tasteless and dissolves easily within seconds. The most common side effect, watery stools or diarrhea, can be easily addressed by scaling back the daily administered dose. As an alternative, if PEG is not available, lactulose (1–2 g/kg, once or twice/day) can be employed (Tabbers et al., 2014).

New medications are being introduced in the therapeutic armamentarium. These have been studied mostly in the adult population yet are expected to slowly transition into pediatrics. New molecules include lubiprostone, linaclotide, plecanatide, and prucalopride (Koliani-Pace and Lacy, 2017; Tabbers et al., 2014). Prucalopride, an oral selective high-affinity $5HT_4$ receptor antagonist with gastrointestinal prokinetic activities, shows particular promise and may represent a reasonable choice for children who fail to respond to more conservative measures (Diederen et al., 2015; Winter et al., 2013).

Maintenance treatment should continue for at least 2 months, and symptoms should be completely resolved for at least 1 month before attempting gradual slow discontinuation. If the child is in the process of toilet training, medication should only be stopped once this developmental milestone has been completely achieved without evidence of further defecation problems. Lack of improvement or worsening should alert the provider to the possibility of reimpaction, lack of adherence with the prescribed medications, insufficient dose, or the introduction of new medications that may worsen constipation. The development of new symptoms, new findings on physical exam, or failure to improve should also renew consideration for underlying organic causes. Refractory cases are most commonly characterized by recurrent fecal impaction, likely because of retentive posturing, anal sphincter dyssynergia, and abnormal rectal motility or function (Bongers et al., 2009; Voskuijl et al., 2006; Youssef and Di Lorenzo, 2002).

Prognosis

Functional constipation can be difficult to treat and a long-lasting problem for some children. Nevertheless, with adequate management close to 50% of patients monitored for 6 to 12 months can recover and successfully discontinue medications, whereas up to 80% can be adequately controlled with routine interventions (Pijpers et al., 2010). Unfortunately, **subsequent recurrences are fairly common, with up to 50% of children experiencing one in the first 5 years after successful treatment** (Loening-Baucke, 1993; van Ginkel et al., 2003). There is a paucity of data on reliable prognostic factors, such as defecation frequency, that could identify patients at risk (Pijpers et al., 2010). Reported figures are clearly affected by the included patient population, and referral specialized centers may evidence lower cure rates despite intensive medical and behavioral therapy, with some children experiencing persistent symptoms beyond puberty, particularly those with older age of onset and initial delay in treatment (Bongers et al., 2010). Importantly, approximately 80% of children adequately managed early in their course recover without need for medications at 6-month follow-up, compared with only 30% with a delay in treatment (i.e., initial medical treatment postponed for >3 months) (Pijpers et al., 2010). Ultimately, data clearly suggest that constipation does not improve without treatment with time or after puberty (van Ginkel et al., 2003). **Early adequate therapeutic interventions are beneficial and may contribute to a successful long-term outcome while improving the child's quality of life.**

Key Points

- Adequate fluid and fiber intake, nonsedentary (active) physical activity, education, and guidance for toilet training should be presented as first-line interventions for all children of adequate developmental age.

- Although of debatable value, interventions with low-risk for adverse effects, such as behavioral therapy or biofeedback, can be considered for interested families.
- PEG should be considered as first-line treatment for constipation (for initiation and maintenance).
- Enemas are of value in the short-term management of children with fecal impaction but are not recommended for routine maintenance treatment.
- Treatment can be gradually discontinued in patients who remain symptom free for at least 1 to 2 months, being vigilant about recurrence.

Surgical Management

A small group of children fail medical management and may be considered candidates for more invasive options. Surgical management of difficult to treat defecation disorders is not a new concept, which has progressed from diversion (colostomy) for the most severe cases to liberal use of enemas and aggressive colon evacuation. With the introduction of the antegrade continence enema (ACE) or Malone (MACE) procedure in 1989, in an attempt to treat the intractable fecal incontinence associated with spina bifida, a new and highly successful option became available (Malone et al., 1990). Koyle subsequently introduced the technique in North America in 1991 (Koyle et al., 1995). The concept behind it is elegant and simple: to provide access to the colon (often at the level of the cecum) to allow regular emptying by means of antegrade instillation of fluid (so-called bowel washout; Fig. 36.15).

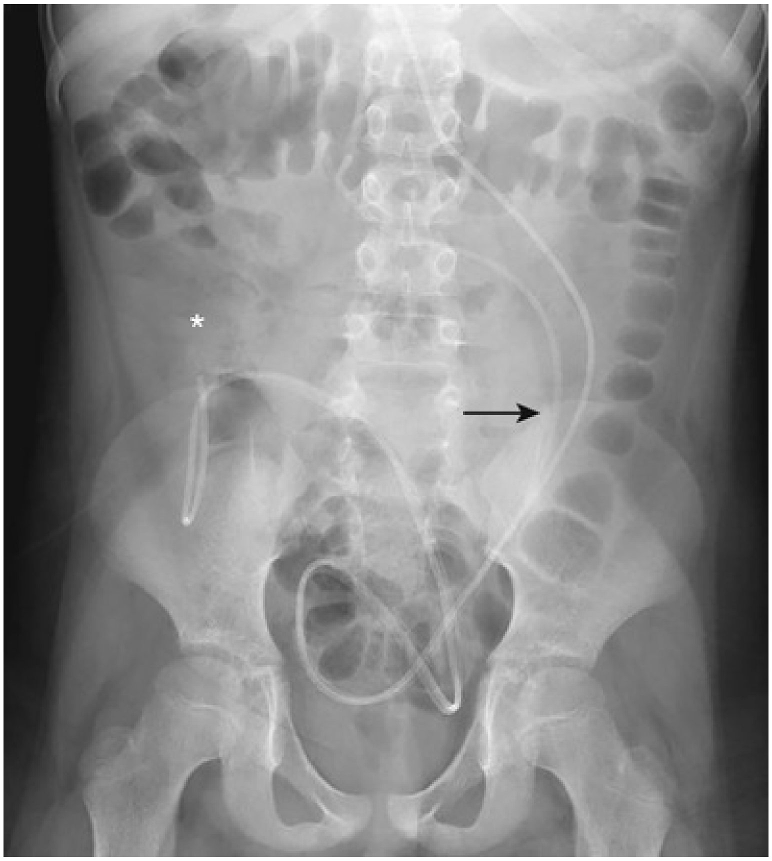

FIG. 36.15 Clearance of large bowel contents with antegrade enemas. Abdominal radiograph taken 12 hours after washout, demonstrating absent fecal material except for early accumulation in the cecum and ascending colon (*). Note presence of a ventriculoperitoneal shunt *(arrow).*

In essence, the MACE combines three well-recognized surgical principles familiar to pediatric urologists and surgeons: (1) complete colonic emptying can achieve bowel continence, (2) antegrade colonic emptying is feasible, and (3) the Mitrofanoff principle of continent cutaneous access to the bladder or bowel is highly successful and reproducible. Based on these, continent intermittent catheter access to the colon for the administration of antegrade enemas while the patient sits on the toilet produces colonic emptying and fecal continence. Success with this approach has been reported in numerous series, and it is now a procedure commonly practiced around the world (Dick et al., 1996; Gerharz et al., 1997a; Griffiths and Malone, 1995; Koyle et al., 1995; Malone, 1995; Peeraully et al., 2014; Schell et al., 1997; Squire et al., 1993).

The initial series described excising the appendix on its pedicle and then reimplanting into the taenia of the cecum, as popularized with the Penn pouch continent urinary reservoir. Modifications have progressed to leaving the appendix in situ and retroverting it (so that the serosa of the colon can be imbricated around it in an anti-refluxing fashion), to not imbricate the appendix (Chan et al., 2018). The procedure can be achieved in an open, laparoscopic, or robotic-assisted fashion (Zee et al., 2017; Fig. 36.16).

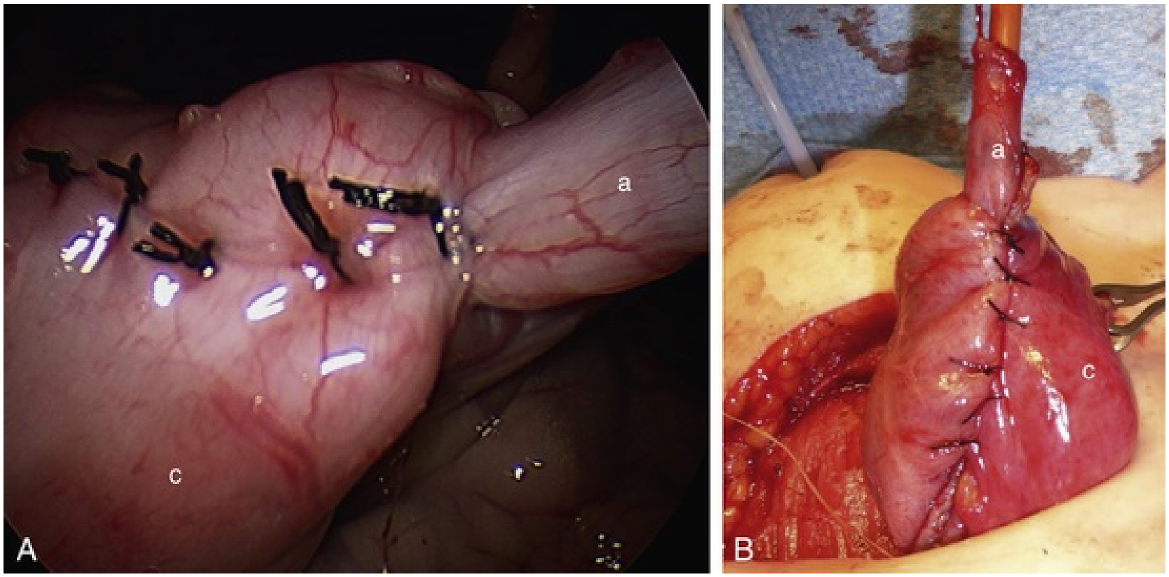

FIG. 36.16 Cecal wrap performed during laparoscopic (A) and open (B) MACE procedure. Note appendix in situ, retroverted with colon serosa imbricated around it in an antirefluxing fashion (*a,* appendix; *c,* cecum).

Nonsurgical Alternatives

In recent years, retrograde washouts have regained interest as a noninvasive way to gain fecal continence in neuropathic and non-neuropathic severe constipation with or without soiling. Although the use of retrograde enemas dates back centuries, the initial concept of using a large-volume saline enema administered through a balloon catheter was developed (Shandling and Gilmour, 1987). In more recent years, commercially available devices (such as the Peristeen transanal irrigation system or the cone-shaped enema tip) have gained some popularity because they provide a more streamlined and patient-friendly way to administer the enemas. The procedure reliably evacuates the descending and rectosigmoid colon in most patients with a variety of defecation disorders (Christensen and Krogh, 2010). Despite a high success rate and growing acceptance, use has been affected by costs and some difficulty with self-administration (Alhazmi et al., 2019; Corbett et al., 2014; Kelly et al., 2017;

López Pereira et al., 2010; Pacilli et al., 2014). This option is a reasonable first step in potential surgical patients, because it may delay or avoid the need for more invasive interventions or provide evidence that regular washouts lead to improvement before committing to antegrade enemas.

Patient Selection and Preparation

For those children in whom conservative measures fail, retrograde enema compliance becomes an issue, or in those who experience successful bowel management through rectal enemas but desire a more convenient means of administration, surgical MACE may be considered an option. Although fecal continence is comparable whether enemas are administered rectally versus antegrade (Matsuno et al., 2010), procedural independence is often optimal for patients performing antegrade enemas. As such, the MACE procedure should be seen as an option that allows patient independence and avoids rectal instrumentation. The underlying diagnosis is important as it influences the success rate. Other issues that may be considered include the presence, length, and quality of the appendix; need and timing of urinary tract reconstruction; patient age and potential intellectual capacity, as well as dexterity, ambulatory status, and body habitus.

Patients with a neuropathic bowel and anorectal malformations seem to fare better than those with chronic idiopathic constipation (Curry et al., 1998). Nevertheless, with increasing experience, modest success rates appear to be improving (Curry et al., 1999; Kokoska et al., 2001; Peeraully et al., 2014). Age at operation is also important, with failures more commonly seen in younger patients irrespective of the diagnosis (Curry et al., 1998). This may reflect inability of young children to sit on a toilet for up to 1 hour before emptying is complete or lack of drive to achieve continence (as seen in older children because of school and peer pressure). Favorable outcomes appear to decrease again after puberty (Christison-Lagay et al., 2010; Gerharz et al., 1997b; Sturkenboom et al., 2018). This may reflect the impact of changes in body habitus associated with transferring issues in those with neurologic conditions, combined attempts at independence with less caregiver support, and compliance issues with the washout regimen.

Just like any other catheterizing protocol, understanding and reinforcing information to the patient and her or his caregivers are essential. It cannot be overemphasized how important ongoing detailed counseling and continued support, pre- and postoperatively (ideally provided by a well-trained dedicated member of the team, such as a nurse practitioner), are to ensure adequate and continued motivation, without which the procedure is set for failure. The ideal patient for a MACE should be between the ages of 5 and 12 years of age, have a diagnosis of neuropathic bowel, anorectal malformation, or Hirschsprung disease, be well motivated with a dedicated family, and have tried and failed all conservative measures.

Operative Technique

Although preoperative bowel preparation may facilitate the initiation of postoperative enemas, an aggressive cleanout is not necessary for the purpose of performing the procedure. Appropriate prophylactic antibiotics are always administered perioperatively and may be adjusted based on any concurrent urinary tract reconstruction. In most instances where coincidental urinary tract surgery is to be performed, a lower midline or Pfannenstiel incision is selected, depending upon the patient's body habitus, prior surgical scars, and surgeon preference. Laparoscopy allows for identification of the appendix and mobilization of the colon, being particularly useful when the cecum is located high in the abdomen, close to the liver (Fig. 36.17). In such cases (often spina bifida patients with prior abdominal incisions and ventriculoperitoneal shunts), a large incision is avoided. In addition, the presence and status of the appendix can be confirmed. If only a MACE channel is to be performed, a pure laparoscopic or robotic approach, or an open appendectomy incision, can be employed, depending on the individual situation and surgeon experience and comfort.

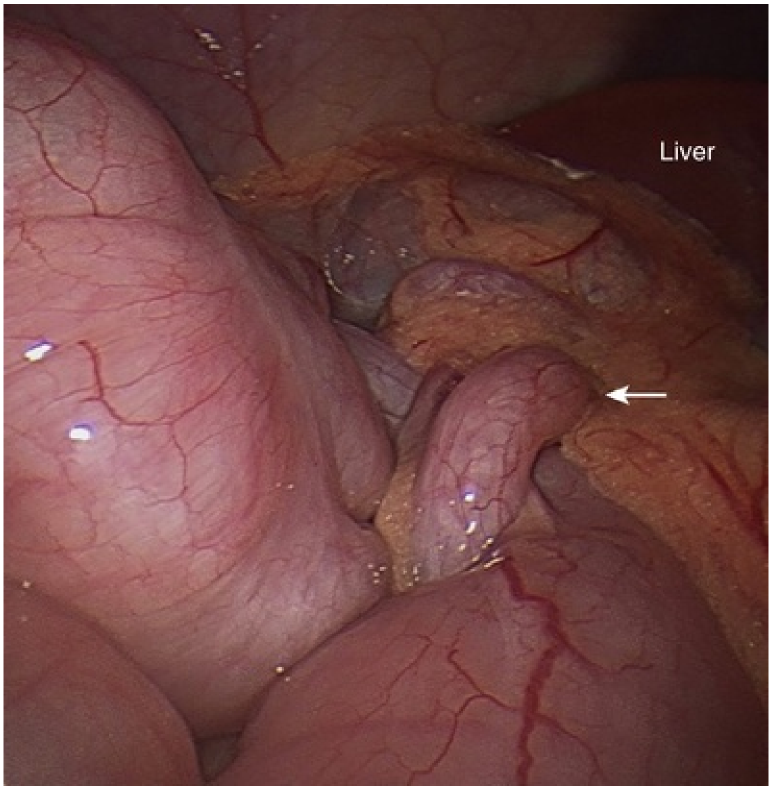

FIG. 36.17 Diagnostic laparoscopy as the initial step to laparoscopic or laparoscopic-assisted MACE procedure. Presence, quality, and location of the appendix can be easily determined. Note location of cecum and appendix *(arrow)* close to the liver in a child with spinal dysraphism.

In most descriptions of the ACE procedure an “antireflux” valve mechanism is fashioned to prevent leakage of bowel contents via the cutaneous stoma. Because the tendency is to maintain the appendix in situ, this is achieved by wrapping it with the cecal wall, an adaptation that follows the principle of the Nissen fundoplication (Koyle et al., 1995). This can be done in a minimally invasive way (Lawal et al., 2011; Nanigian and Kurzrock, 2008; Webb et al., 1997). To reduce the risk of compromising blood supply to the appendix, its mesentery is fenestrated to allow passage of sutures and tissue without entrapping the vessels (Fig. 36.18). The colon can also be sutured to the posterior aspect of the anterior abdominal wall to ensure that the catheterizable conduit is not lying free in the peritoneal cavity, preventing kinking and difficulties with catheterization. Recently it has been suggested that it is not necessary to construct an antireflux mechanism, and some have advocated avoiding this step and simply mobilizing the appendiceal-cecal unit to the abdominal stoma site, a procedure that is amenable to a purely laparoscopic or robotic-assisted approach (Fig. 36.19; Chan et al., 2018; Thakre et al., 2008;

Webb et al., 1997). Thus far, data appear to support similar rates of stomal bowel incontinence, based on retrospective reviews comparing MACE with and without cecal wrap (Chan et al., 2018; Koivusalo et al., 2006; Nanigian and Kurzrock, 2008).

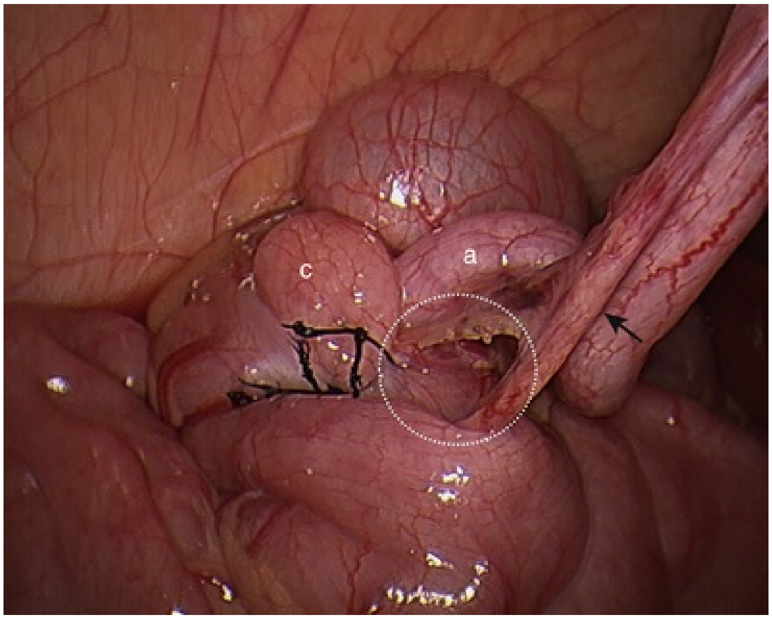

FIG. 36.18 Fenestration of the appendix mesentery during laparoscopic MACE procedure, allowing passage of suture and creation of a cecal wrap without compromise of the blood supply *(arrow)* (*a,* appendix; *c,* cecum).

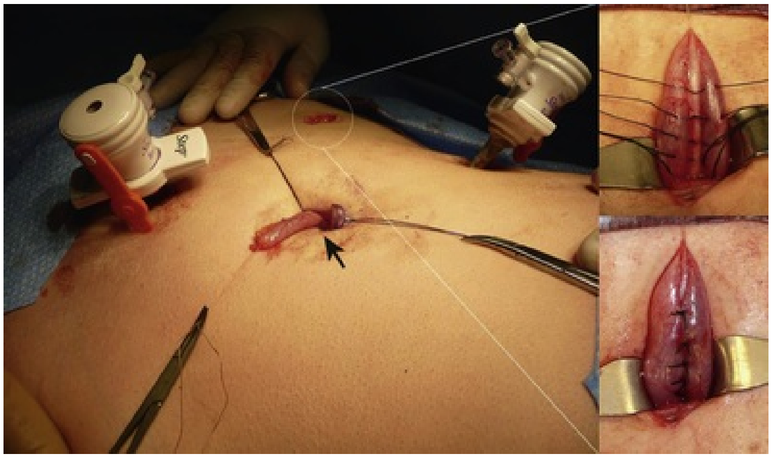

FIG. 36.19 Laparoscopic-assisted cecostomy tube take-down and creation of MACE channel with appendix. Open imbrication through C-tube scar allows creation of “antireflux” mechanism. Note tip of appendix delivered through camera port at umbilicus *(arrow).*

If the patient requires synchronous bladder reconstruction, simultaneous MACE and Mitrofanoff urinary diversion offers patients the chance for complete dual fecal and urinary continence (Casale et al., 2006; Roberts et al., 1995; Wedderburn et al., 2001). The technique must be modified if MACE and appendicovesicostomy procedures are being considered. If the appendix is long enough and the vascular anatomy is suitable, it is possible to split the appendix (Fig. 36.20). If the appendix is not suitable to be split or is absent, alternative options must be considered. In these cases tubularized colon flaps (Fig. 36.21) or cecal extension of the appendiceal stump with a surgical stapler (Fig. 36.22) can be done with relative ease, achieving good results with acceptable complication rates (Anselmo et al., 2017; Herndon et al., 2005; Kiely et al., 1994). The Monti-Yang procedure can also be employed as an alternative conduit (Monti et al., 1997), following the Mitrofanoff flap valve principle to implant in the bowel wall. Some advocate this option as the procedure of choice when the appendix is not available (Sugarman et al., 1998); it can be particularly advantageous in very obese patients, because the use of a spiral or two segments of bowel will produce a conduit long enough for almost all patients.

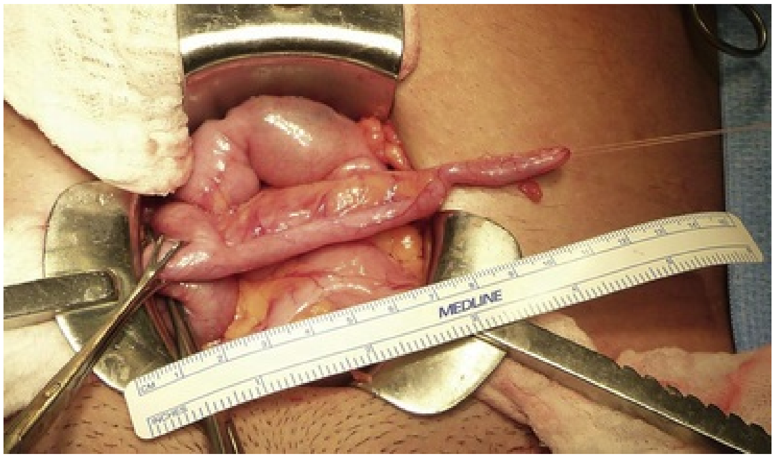

FIG. 36.20 Long appendix with robust blood supply, amenable to split for simultaneous MACE channel and appendicovesicostomy.

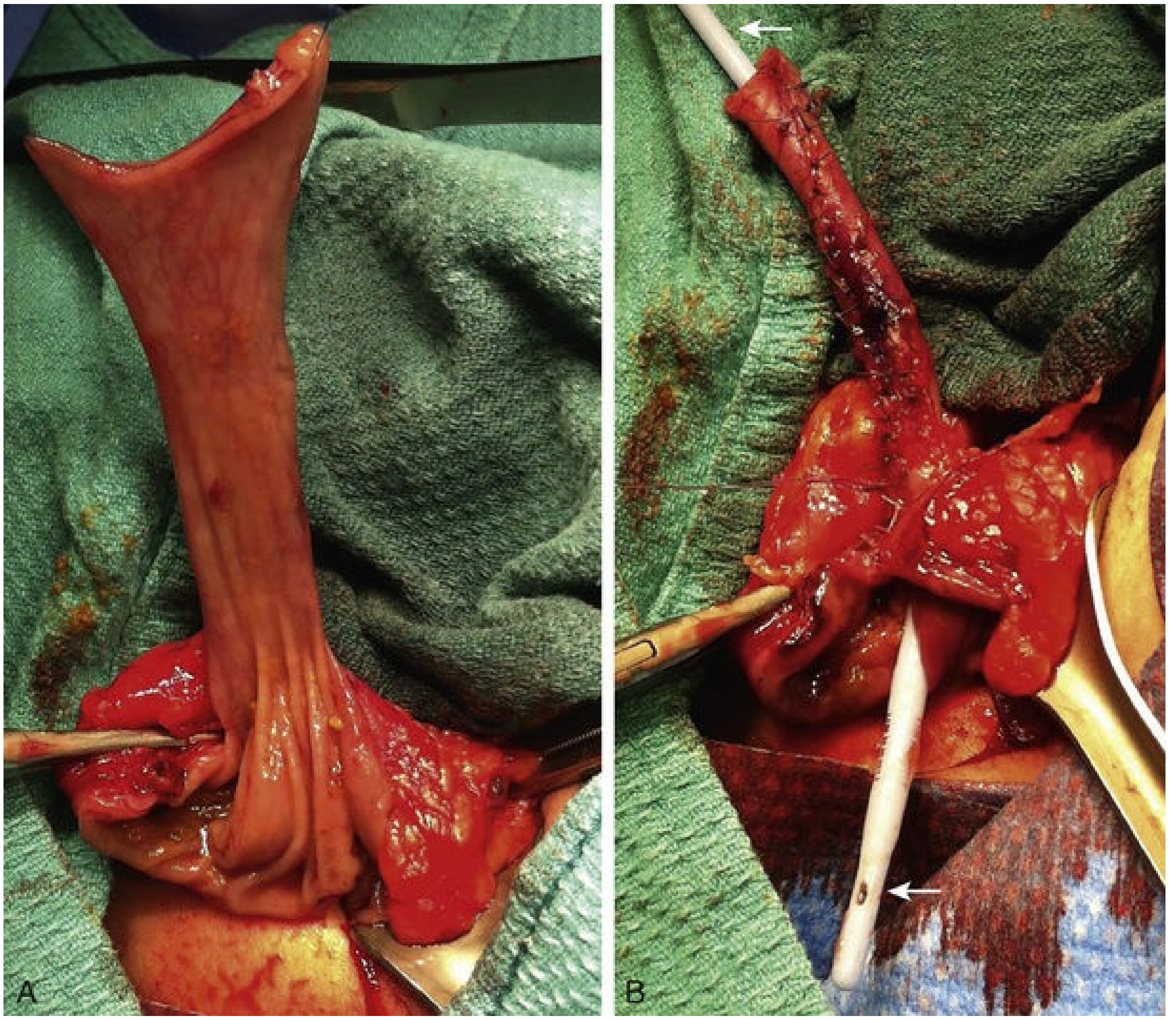

FIG. 36.21 Creation of access with a colon flap (A), tubularized and subsequently imbricated (B). This is suitable for catheterization for flushes to the left or right colon.

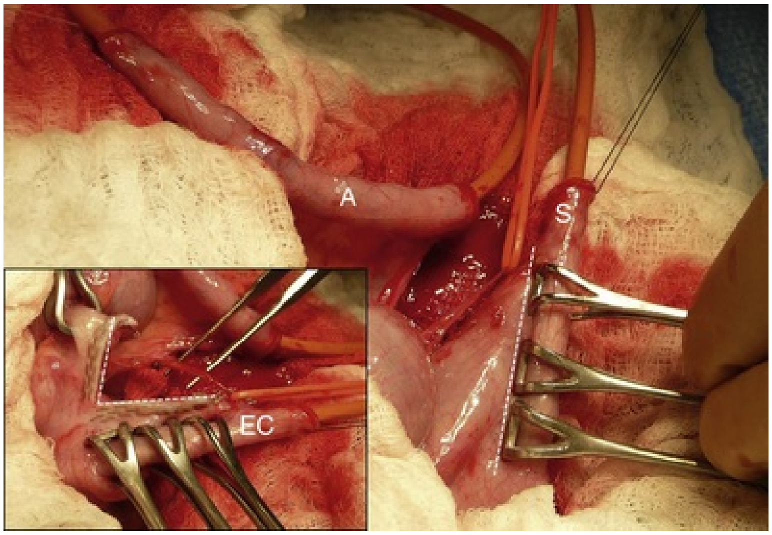

FIG. 36.22 Technique for cecal elongation of appendiceal stump with a surgical stapler effectively lengthening the channel, which is subsequently imbricated to prevent leakage (*A,* distal segment of appendix preserved for appendicovesicostomy; *EC,* elongated cecum; *S,* appendiceal stump).

Another option worthy of consideration is the use of either a cecostomy tube (C-tube or cecal button). Since the description by Chait et al. (Chait et al., 1997a,b), the technique for percutaneous placement of a cecal tube that can be regularly exchanged as a permanent, low-profile cecal button (similar to a gastrostomy button) has been refined. The cecostomy tube option is favored when the appendix is known to be absent (i.e., postappendectomy), when the patient refuses to perform intermittent bowel catheterization, for patients who develop stomal complications such as stenosis (as an alternative to revision of the MACE channel), as a temporary therapeutic challenge to determine response to antegrade enemas, or to determine if ideal placement of a permanent MACE should be in the right or left colon, and as a permanent option in cases in which a nonoperative access is favored. Long-term outcomes reported by Chait et al. (1997a), who performed the procedure percutaneously under fluoroscopic guidance, show successful placement in a large number of children with satisfactory outcomes, certainly similar to other approaches (Chait et al., 2003). The tube can also be placed open or under laparoscopic guidance at the time of concomitant appendicovesicostomy (Lorenzo et al., 2007). The main drawback is that the tube entry site can become unsightly, with granulation tissue and occasional fecal leakage (Fig. 36.23). In these cases, patients may opt for subsequent formal conversion to a bowel-based MACE, either laparoscopic or open (Fig. 36.24). Regardless, the tube or button can always be converted to a formal ACE with time, thus providing a reasonable initial option and bail out in complicated cases.

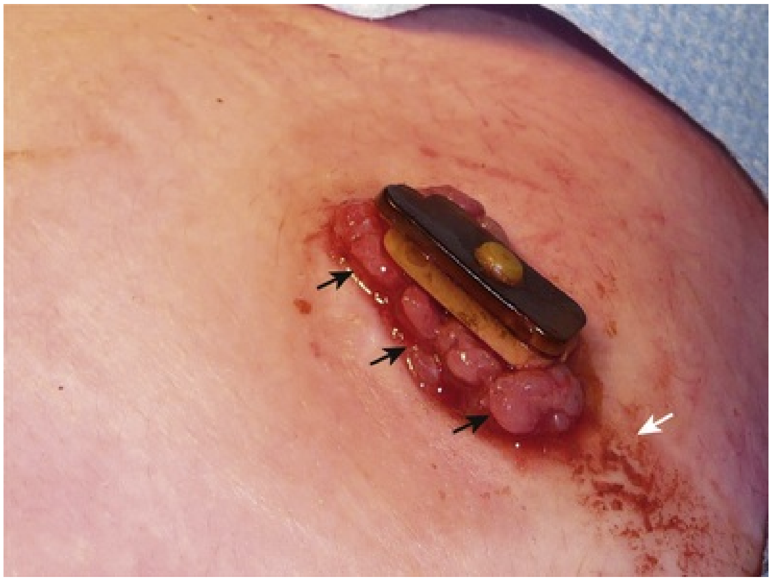

FIG. 36.23 Granulation tissue *(black arrows)* and leakage *(white arrow)* around cecostomy tube. Unsightly appearance and soiling can occur over time, which can lead to removal or conversion to a MACE channel.

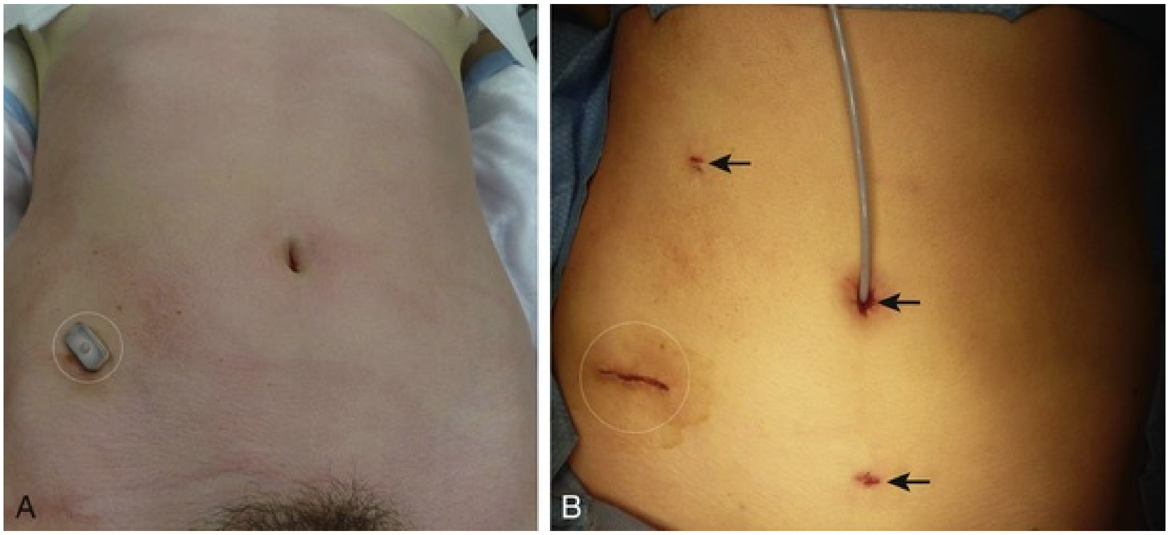

FIG. 36.24 Port placement *(arrows)* and cosmetic outcome of C-tube takedown and laparoscopic-assisted MACE creation (preop [A] and immediate postop [B]).

One of the problems occasionally encountered, particularly in children and adolescents with severe constipation and a redundant colon (Fig. 36.25), is the long time for the washout to actually work. This issue can lead to frustration, failure, and abandonment of the irrigations (Griffiths and Malone, 1995). In an attempt to rectify this problem, some have advocated placing the conduit in the left colon, rather than the cecum (Ellison et al., 2013). By doing so, the length of bowel that has to be washed through is reduced and theoretically so is the time taken for successful enema completion. Results using this approach have been encouraging, with similar outcomes and complication rates compared with traditional MACE (Blackburn et al., 2012; Churchill et al., 2003; Liloku et al., 2002; Meyer et al., 2008; Sinha et al., 2008), yet with less enema fluid requirements and shorter transit times (Sinha et al., 2008). A left MACE should strongly be considered in patients suffering from severe constipation. The decision between left or right access may be a difficult one and can be settled by temporarily placing a cecostomy or percutaneous colostomy tube. If equivalent or better on the right, then the in situ appendix is the simpler option.

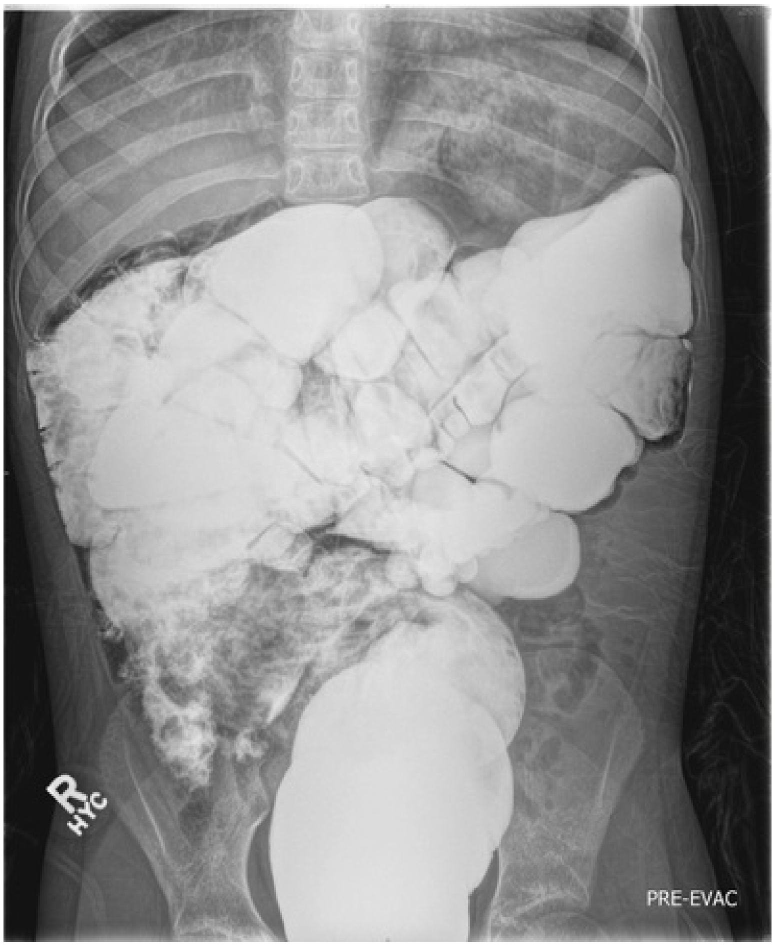

FIG. 36.25 Contrast enema study in a child with long-standing constipation demonstrating redundant colon without associated anatomic abnormalities or radiologic evidence of Hirschprung disease.

Enema Regimen

Although protocols differ, the first enema is commonly administered via the indwelling catheter or percutaneously placed tube after the postoperative ileus resolves, followed by a progressive escalation titrated to the desired effect. Considering individual patient needs and variable response, there is much “trial and error” involved. One of the most important points, especially in the early weeks and months after surgery, is to advise patients not to expect immediate success, because early disappointment can lead to frustration and failure. In fact, many children may not achieve a steady state or a reliable enema routine for a period of up to 6 months (Curry et al., 1998). Patients may also experience a degree of rectal leakage within the first few hours after the washout, but this does not appear to be a long-term problem. Although the washout regimen is established outside the hospital, it is vital to maintain regular contact with the nurse specialist who helps manage the process.

Enema protocols differ among centers, and patients and families frequently modify them to suit their own particular needs. Initially, daily washouts with 20 mL/kg of solution are encouraged, but once the patient is comfortable with the process and a routine has been established, they may attempt to decrease frequency to alternate days. The time of day that the enema is administered is patient dependent, although most families prefer to give the enema during the early evening hours, after dinner. This time is chosen to allow a sufficient interval to achieve the desired result before bedtime. Rarely, others learn that twice-daily cleanouts are necessary and adjust their frequency accordingly. Washout times range between 30 and 60 minutes. Because patients have to sit on the toilet for a long time, buttock pressure sores may develop, a complication that can be minimized with the use of padded toilet seats. Purges can be done with large-volume tap (Koyle et al., 1995; Yerkes et al., 2001) or salt water, with the judicious mix of additives such as glycerin, Bisacodyl, phosphate, magnesium citrate, mineral oil, or polyethylene glycol. Although uncommon, and depending on the solution used, water intoxication and/or electrolyte abnormalities may occur (Hunter et al., 1993; Schreiber and Stone, 1999). Changes and experimentation should only be done under supervision to minimize this risk. Once a steady state is achieved, there is little benefit from dramatically interfering or modifying the regimen.

Several difficulties can be experienced during enema infusion. The most common problem is pain or discomfort during instillation (Curry et al., 1998). In the majority of patients, this is a transient phenomenon that subsides during the first 3 months. Persistence beyond this time period can contribute to discontinuation. Warming the solution, lowering additive concentration, reducing the rate of the infusion, adding sodium chloride, or using an antispasmodic before the enema can be tried in these cases. It is always important to ensure that the pain is not due to distal fecal impaction (Fig. 36.26), which can occur despite regular washouts. These patients may require occasional retrograde cleanouts or be candidates for re-positioning the location of the access channel in the colon (cecum vs. right colon) (Churchill et al., 2003; Liloku et al., 2002).

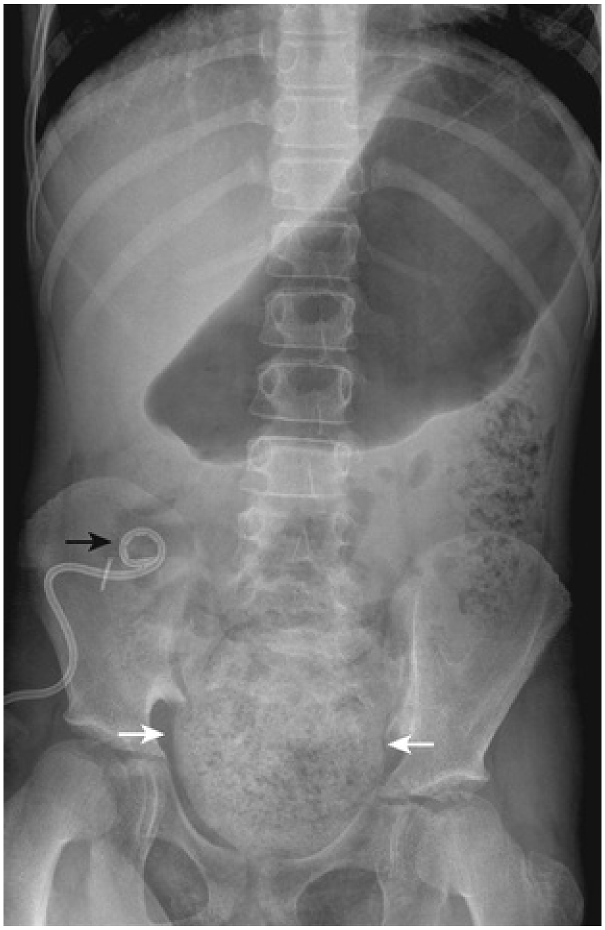

FIG. 36.26 Presence of a large amount of fecal material in the distal colon and rectum *(white arrows).* This patient became impacted while doing infrequent antegrade enemas through a cecostomy access *(black arrow).*

Attempts at clearing this fecal load with antegrade flushes only led to abdominal pain, lack of tolerance, and poor response. Improvement was achieved with disimpaction and retrograde enemas followed by diligent, regular antegrade flushes to achieve complete washout.

Surgical Outcomes

In a survey of 300 ACE procedures performed by members of the British Association of Paediatric Surgeons (BAPS), Curry et al. (1999) reported that success rates were dependent on the original diagnosis (Table 36.4). This large national series reported an overall full and partial success rate of 79%, with complication rates that were lower than in earlier historical series. In particular, stomal stenosis rates were reduced to 30%.

TABLE 36.4

MACE Procedure Success and Failure[a] Based on Underlying Condition

DIAGNOSIS	FULL SUCCESS %	PARTIAL %	FAILURE %
Spina bifida	63	21	16
Anorectal malformation	72	17	11
Hirschsprung disease	82	9	9
Idiopathic constipation	52	10	38
Other	44	25	31

[a] Surgical results have been classified as follows (16): Full success: totally clean or minor rectal leakage on the night of the washout; partial success: clean but significant rectal leakage, occasional major leak, still wearing protection, but perceived by the parent or child to be an improved; failure: regular soiling or constipation persists, no perceived improvement, and the irrigations are abandoned.

Standardized tools have been employed to reflect improvements in quality of life (Shankar et al., 1998), self-esteem, psychosocial function (Aksnes et al., 2002), and fecal incontinence and constipation-related quality of life (including anxiety and family worry) (Ok and Kurzrock, 2011). Nonvalidated questionnaires have shown high satisfaction rates, with a majority of respondents recommending the procedure to others with intractable defecation disorders (Hoekstra et al., 2011).

For patients undergoing synchronous bladder reconstruction and ACE procedures, a high percentage of fecal and urinary continence should be expected, with variable complication rates (Kajbafzadeh and Chubak, 2001; Wedderburn et al., 2001) and no adverse impact compared with patients undergoing staged reconstruction (Casale et al., 2006). Stomal complications and difficulty catheterizing the conduits remain the most important postoperative problems (Barqawi et al., 2004). For example, Curry et al. (1998) reported an incidence of 55% for stomal complications. Ransley's VQZ-flap has been advocated as a technique to reduce the incidence of stenosis when the MACE is directed to a position other than the umbilicus (Landau et al., 2008; Malone et al., 1998; McAndrew and Malone, 2002). Conduit perforation and intraperitoneal enema instillation occurs rarely (3.7% over a 13-year period) but can result in significant morbidity and need for emergency surgical exploration (DeFoor et al., 2005). If suspected, a contrast study through the channel may help establish the diagnosis (Fig. 36.27).

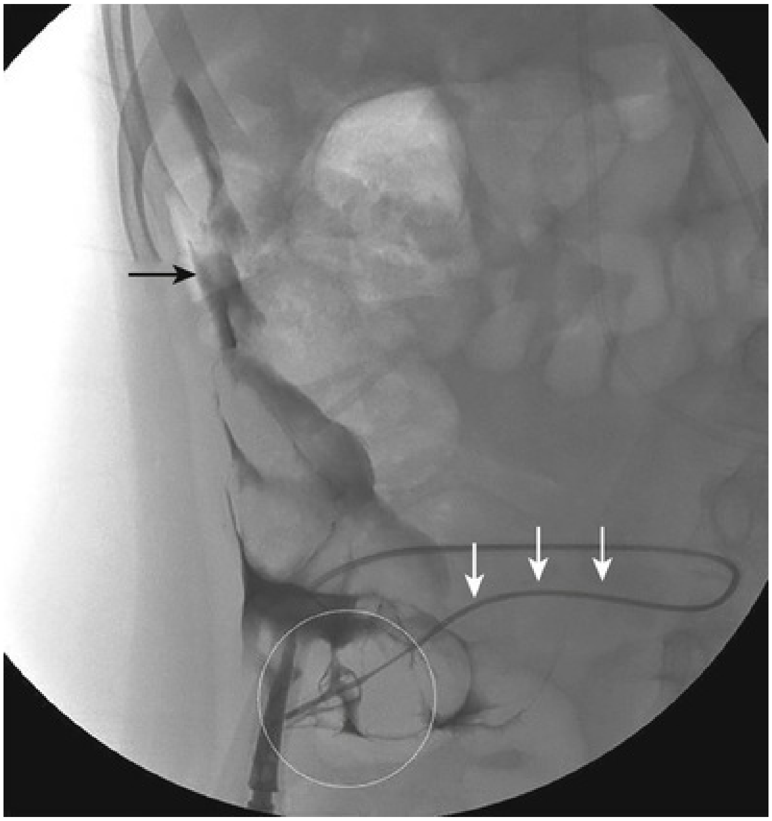

FIG. 36.27 Water-soluble contrast study through catheter placed in MACE channel *(white arrows)* to evaluate possible perforation *(black arrow).*

Key Points

- Surgical management of defecation disorders has been revolutionized with the concept of antegrade enemas, delivered through a catheterizable channel (MACE) or a cecostomy tube. This enables the patient to evacuate the colon at regular intervals, avoiding impaction and reducing fecal incontinence.
- Retrograde (transanal) washouts with a balloon catheter in the rectum represent a viable and less invasive alternative, which is gaining popularity in the management of neuropathic and non-neuropathic defecation disorders.
- Patient selection is critical, and candidates should have failed maximal conventional measures before proceeding to invasive options.
- Although individual variations are expected, patients commonly do washouts on a regular basis (daily or every other day) to achieve continence.
- Concurrent reconstruction of the gastrointestinal and genitourinary tract is feasible in most cases, with adaptations to fashion access to bladder and bowel employing available bowel segments.
- Surgical options include open, laparoscopic, robotic-assisted, and percutaneous techniques.

Lower Urinary Tract Reconstruction in Children

John C. Thomas MD, FAAP, FACS, Douglass B. Clayton MD, FAAP, Mark C. Adams MD, FAAP

Although children with anomalies affecting the bladder and outlet are managed with a primary goal of minimizing the need for operative intervention, the basic functions of a “normal” lower urinary tract—to protect renal function, avoid urinary tract infection (UTI), and eventually provide urinary continence—must be achieved. Surgical reconstruction remains an important and effective tool for some children. When reconstruction is considered, it is imperative that the patient be thoroughly evaluated. Each child is unique, and his or her particular pathophysiology must be understood so that surgical techniques available may be used thoughtfully to optimize results while minimizing morbidity.

The scope of this chapter is large. Augmentation cystoplasty is reviewed in detail. In few areas of urology have intestinal segments been used as extensively. Complex patients with bladder dysfunction may also have bladder neck and external sphincteric problems, and this chapter covers techniques that increase bladder neck and external urinary sphincter resistance in the pediatric population. **Perhaps the most important contribution affecting lower urinary tract reconstruction was the introduction of clean intermittent catheterization (CIC) by Lapides et al.** (1972, 1976) **based on the work of Guttmann and Frankel** (1966). Because many pediatric patients with bladder and sphincteric dysfunction do not void adequately after reconstruction, creation of a reliable means to easily catheterize may be essential; ways to do so are presented, along with related results in children.

Most pediatric lower tract reconstructive procedures are undertaken primarily to correct hostility in the native lower urinary tract unresponsive to medical management. Children with bladder and sphincteric dysfunction are among the most complex seen in pediatric urology, and those with spina bifida make up the majority of patients requiring this type of surgical

intervention. The results discussed herein therefore focus on the neurogenic population. **The most important factor influencing the outcome of urinary tract reconstruction in children is the commitment of the patient and family to achieving good care.** Determining that commitment may at times be difficult, but its importance should not be underestimated.

“Functional” Urinary Tract

Bladder physiology can be characterized in two dynamic phases: passive and active. During the passive storage phase, the bladder functions as a reservoir, allowing for urine to be stored at low pressure without leakage. In the active voiding phase, the bladder contracts and efficiently eliminates urine.

Dysfunction

Upper Urinary Tract

It is critical to understand the dynamics of the entire urinary tract before any major reconstructive procedure. In the presence of hydronephrosis, upper tract obstruction must be excluded. Upper tract obstruction may be secondary to severe, long-standing bladder hostility involving poor bladder compliance and emptying. Nuclear renography with a urethral catheter may be useful to rule out a primary upper tract obstruction. Upper tract obstruction, if present, should be corrected at the time of bladder and sphincter reconstruction.

Vesicoureteral reflux in the presence of bladder hostility may be primary or secondary, and differentiating the two may be difficult. If reflux was not present during earlier evaluation, new onset is likely secondary to bladder hostility. Reflux in children with neurogenic dysfunction is often secondary. Previous work has suggested that reflux secondary to bladder hostility may not need surgical correction if the bladder is adequately managed. Neurogenic bladder requiring augmentation in children who did not undergo reimplantation for secondary reflux resolved with augmentation alone (Juhasz et al., 2008; López Pereira et al., 2001; Morioka et al., 1998; Nasrallah and Aliabadi, 1991; Soylet et al., 2004). It is interesting to speculate whether reflux is even a significant problem if a large, compliant bladder is achieved (Soylet et al., 2004). Bacteria may ascend with or without reflux after reconstruction, and certain forms of continent diversion have not shown an increased risk of pyelonephritis in the absence of any antireflux mechanism when compliance is adequate (Gonzalez and Reinberg, 1987; Helal et al., 1993; Pantuck et al., 2000). We agree that most secondary reflux will likely resolve with adequate reconstruction of the bladder but will correct high-grade reflux if present. Caution is warranted when considering the treatment of chronically dilated and scarred ureters. Correcting reflux in that setting is appropriate but can result in obstruction if overly aggressive tapering or tunneling is performed (Hendren, 1998).

Dysfunction in the upper urinary tract usually manifests with hydronephrosis, pyelonephritis, or impairment of renal function. When such problems are present in patients with lower tract dysfunction, thoughtful evaluation and treatment are necessary. All problems should be addressed before and at the time of reconstructive surgery to achieve the best result.

Bladder Dysfunction

Bladder dysfunction is a composite of physiologic abnormalities, and it is helpful to assess each component of passive and active bladder function independently. **Elevated passive filling pressure becomes clinically pathogenic when a pressure greater than 40 cm H_2O is chronically reached** (McGuire et al., 1981; Wang et al., 1988; Weston et al., 1989). Pressures at this level sustained over a period of time impair ureteral drainage that may result in pyelocalyceal changes, hydroureteronephrosis, and decreased glomerular filtration rate. In addition, persistent elevation in filling pressure can result in acquired vesicoureteral reflux (Cohen et al., 1990; Sidi et al., 1986a).

Pharmacologic management can play a role in decreasing filling pressure, particularly when overactive detrusor contractions are present. A combination of medications and intermittent catheterization have a positive impact, particularly in children with neurogenic dysfunction (Aslan and Kogan, 2002; Rink and Mitchell, 1984; Verpoorten and Buyse, 2008). When compliance is unaffected by medical management, augmentation cystoplasty may be required to improve the storage characteristics. After reconstruction, the likelihood of efficient detrusor contractions and effective emptying of the bladder is diminished. Intermittent catheterization should be taught and accepted by the patient and caretaker preoperatively. CIC allows the reconstructive surgeon to aggressively correct storage problems through augmentation. Spontaneous voiding, although a goal, is not imperative because CIC can be used for emptying.

Urinary incontinence is a prominent sign of bladder dysfunction. Continence requires outflow resistance generated by the bladder neck and external urinary sphincter. Outflow resistance must remain greater than bladder pressure during storage throughout normal daily activity. When outflow resistance is diminished because of an abnormal bladder neck and external urinary sphincter, incontinence often occurs. Pharmacologic management with α-adrenergic agents can enhance outflow resistance, but more commonly operative reconstruction is required.

When incontinence occurs during the filling phase because of poor outlet resistance, it is essential to evaluate not only the bladder neck and external urinary sphincter but also detrusor characteristics. Clinical experience has shown that once appropriate resistance is achieved at the bladder neck through operative intervention, adverse detrusor characteristics may become unmasked and result in high pressure urinary storage or uninhibited contractions not previously documented (Bauer et al., 1986; Churchill et al., 1987; Dave and Salle, 2008). For that reason, provocative urodynamic assessment with occlusion of the bladder neck is important before any bladder neck reconstruction in an attempt to identify children who will be at risk.

Normal synergistic voiding occurs when the bladder neck descends, relaxes, and opens, followed by relaxation of the external urinary sphincter and subsequent detrusor contraction resulting in low pressure voiding. Dysfunctional voiding during this active bladder phase occurs as a result of uncoordinated activity of the bladder neck, external urinary sphincter, and detrusor. With such dyssynergy, high-pressure voiding results that chronically can negatively affect the bladder and upper urinary tract (Bauer et al., 1984; Mundy et al., 1982). A similar clinical situation occurs with a fixed, fibrotic external sphincter. Initial treatment involves pharmacologic management and CIC in an attempt to bypass the abnormal voiding mechanics.

Other Considerations

Renal function should be assessed in any patient undergoing bladder reconstruction, particularly if hydronephrosis or severe renal scarring is present. **Demos** (1962) **and Koch and McDougal** (1985) **have demonstrated that urinary solutes, particularly chloride, are absorbed from urine in contact with the mucosa of small and large bowel.** For patients with normal renal function, the kidneys are able to handle the reabsorbed load of chloride and acid without obvious difficulty. Patients with decreased renal function, however, may develop significant metabolic acidosis secondary to such reabsorption. If acidosis exists preoperatively, it will invariably worsen if urine is stored in small or large intestinal segments (Mitchell and Piser, 1987). The first component of renal function to deteriorate after obstruction or infection is concentrating ability. Patients with compromised function may generate enormous volumes of urine. **The bladder volume achieved through bladder reconstruction must accommodate the patient's urinary output for an acceptable period of time,**

usually 4 hours. Patients with renal failure or other medical problems may conversely develop oliguria. Low urinary output may affect an augmented bladder or bowel reservoir with greater collection and inspissation of mucus.

Abnormal function of other organ systems also influences the risk of bladder reconstruction using intestinal segments. Reabsorption of ammonia by large or small intestinal segments in contact with urine may be dangerous for patients with hepatic failure (McDougal, 1992a). Some medications excreted in urine may be reabsorbed by bowel mucosa (Savauagen and Dixey, 1969). Therefore liver function tests and arterial blood gas studies may be appropriate. Careful history should be taken regarding the patient's preoperative bowel function; this is particularly true of patients who may have acquired or secondary gastrointestinal problems. Short gut syndrome is a concern among children with cloacal exstrophy, prior bowel resections, or a history of significant radiation. A history of chronic diarrhea or fecal incontinence preoperatively should signal concern about use of the ileocecal valve in urinary reconstruction.

A critical factor to consider is the commitment of the patient and family. Urinary incontinence, at times, protects some patients from infection and upper tract deterioration. Effective storage can put the patient at risk for problems if emptying is not accomplished on a regular basis. All must be aware of the responsibility that goes along with bladder reconstruction and urinary continence.

The timing of surgical intervention varies dramatically among patients. It may be necessary to perform reconstruction early when the upper tracts and renal function are threatened. This situation may occur in the presence of high outflow resistance and poor bladder compliance. Although work has suggested that augmentation cystoplasty to correct bladder hostility may slow deterioration of renal function even when renal insufficiency resulting from secondary upper tract damage is already established (Ivancic et al., 2010), early intervention to prevent such damage is preferable. More commonly, reconstruction is undertaken later to achieve urinary continence. The age at which urinary incontinence, or the presence of a urinary stoma after temporary diversion, becomes socially unacceptable varies among patients and families.

It is beneficial for the patient and family to wait for bladder reconstruction until all needs of the child are identified. This is not always possible when intervening because of infection or hydronephrosis. When reconstruction is undertaken to achieve continence, it is most efficient to identify all reconstructive issues and address them with one operation. Urodynamic assessment is usually necessary to determine whether a procedure to increase outflow resistance is necessary in addition to bladder augmentation or replacement. Introducing CIC preoperatively is mandatory in that it allows the patient to demonstrate the ability and desire to continue on a regular basis. It is also helpful in determining whether a continent abdominal wall stoma may be required to improve the reliability of catheterization and increase the patient's independence. Likewise in the neurogenic population, it is advantageous to identify the child who may benefit from an antegrade colonic enema. It is certainly better for the patient and surgeon to address all of these issues at one time rather than with sequential procedures that may add morbidity.

Patient Evaluation

Each patient should have upper tract imaging before bladder reconstruction; most will have had routine ultrasonography as part of their surveillance. **When hydronephrosis is present, imaging should be performed to assess for obstruction or vesicoureteral reflux.** Nuclear renography with a catheter in the bladder is usually adequate to rule out primary upper tract obstruction. Reflux should be excluded with an independent voiding study or as part of video urodynamics. In the presence of hydronephrosis, patients should have obtained baseline levels of serum electrolytes, blood urea nitrogen (BUN), and serum creatinine. Patients with elevation of the serum creatinine or significant hydronephrosis benefit from nephrologic evaluation and a 24-hour urine collection for creatinine clearance and urine volume.

Special attention must be given to patients after prior urinary diversion. Permanent intestinal diversions in children are now typically confined to patients requiring cystectomy for cancer. Most urinary diversions performed today are temporary. **The key to urinary undiversion is to understand the original pathology that led to diversion.**

Urodynamics

Bladder Dynamics: Capacity and Compliance

Urodynamic testing of the lower urinary tract plays an essential role when considering bladder reconstruction. Results in infants and children are reproducible but require meticulous attention to detail (Joseph, 1994). Several mechanical factors adversely influence urodynamic data, creating artifacts that, if not recognized, can have a negative impact on the validity of the evaluation. Testing is typically performed with transurethral catheter placement. The size of the catheter can influence the measured leak point pressure, voiding pressure, and ability to empty completely, particularly in infants and young boys (Decter and Harpser, 1992). Suprapubic catheter placement circumvents this problem but is not practical in most cases. The testing medium and infusion rate can influence the results. Carbon dioxide is not as reliable as fluid infusion, particularly when evaluating bladder compliance and capacity. Most commonly, saline or iodinated contrast is used at body temperature to provide reproducible results (Joseph, 1993, 1996). End filling pressure, and therefore bladder compliance, can be dramatically affected by simply changing the filling rate (Joseph, 1992). Bauer (1979) suggested that the cystometrogram be performed at a fill rate of no greater than 10% of the predicted bladder capacity per minute. Despite these advancements and contributions made to improve the reliability and validity of urodynamics in this patient population, significant interrater interpretative variability still exists even amongst providers at the same institution (Dudley et al., 2017). In a follow-up multi-institutional study, the same author confirmed only fair agreement among providers with electromyleography (EMG) synergy and/or presence of detrusor overactivity (Dudley et al., 2018).

Special nuances may be necessary after diversion by vesicostomy. Any bladder is likely to show small capacity in that setting. A repeated study after several days of bladder cycling by occlusion of the vesicostomy may be more predictive of bladder function; the bladder may respond to cycling quickly (Errando et al., 2005; McGuire, personal communication, 1996). Temporary occlusion of the ostomy with a gastrostomy button may be informative (de Badiola et al., 1995).

Sphincter Dynamics: Outflow Resistance

The bladder neck and external urinary sphincter work in synergy, but only one is required for maintenance of urinary continence. Neurogenic dysfunction often leads to abnormalities of the bladder neck and external urinary sphincter, resulting in diminished outlet resistance during storage and/or dyssynergic function with voiding. Monitoring of external urinary sphincter electrical activity is required for evaluation of coordinated voiding and dyssynergic detrusor sphincter activity. Perineal surface electrodes, abdominal wall sensors, anal plugs, vaginal monitors, electrical wires, and concentric needle electrodes have been used for electromyography (Joseph, 1996). In children with neurogenic dysfunction, a concentric needle electrode or dual needle electrodes placed through a 25-gauge needle increase accuracy when measuring sphincter activity (Blaivas et al., 1977; Joseph, 1996).

The functional length of the external urinary sphincter also plays a role in outflow resistance, and its measurement can be undertaken with urethral pressure profilometry (UPP). Unfortunately, the short length and small diameter of the pediatric urethra makes this study technically challenging because the mechanical pulling device is not practical for pediatric use. To perform UPP, a constant infusion of testing medium at a rate of 2 mL/min using a continuous Harvard pump is required (Joseph, 1996), eliminating pressure wave artifacts noted with the standard roller ball infusion pumps. Hand withdrawal of the catheter is used, marking every 5 mm on the recording strip. With experience and a cooperative patient, reliable measurements can be obtained. There is limited value comparing specific UPP results for a patient against standard nomograms; however, preoperative UPP for a given patient provides baseline information that can be beneficial when assessing the intraoperative and postoperative functional urethral length.

Some surgeons use leak point pressure to evaluate outflow resistance during passive filling and Valsalva. The leak point pressure may be artifactually elevated by the urodynamics catheter in a small male urethra (Decter and Harpster, 1992). Work remains to determine how well such measurable parameters correlate. Khoury et al. (2008) suggest that the presence of bladder trabeculation often predicts that outlet resistance is adequate and that such patients are likely to do well with augmentation cystoplasty alone.

Bladder Emptying

The patient's ability to empty the bladder before reconstruction should be assessed carefully. Parameters influencing bladder emptying include synergistic relaxation of the external sphincter on electromyography, urinary flow rates, and residual postvoid urine. Neurologically intact patients able to empty their bladder well preoperatively are much more likely to do so after reconstruction than are patients with neurogenic dysfunction. **No test ensures that a patient will be able to void spontaneously and empty well after bladder augmentation or other reconstruction.** Therefore all patients must be prepared to perform CIC postoperatively. The native urethra should be examined for the ease of catheterization. Ideally, the patient should learn CIC and practice it preoperatively until the patient, family, and surgeon are comfortable that catheterization can and will be done reliably. Physical and psychosocial limitations of the patient must be considered with regard to the ability to self-catheterize and perform independent care. **Failure to catheterize and empty reliably after bladder reconstruction may result in upper tract deterioration, UTI, or bladder perforation despite a technically perfect operation.** Most patients who may catheterize per native urethra or an abdominal wall stoma overwhelmingly prefer the latter (Horowitz et al., 1995).

Patient Preparation

Bladder and sphincter reconstructive procedures remain challenging. The patient's general status should be optimized to afford the best chance to achieve a good result with the least risk of morbidity. General nutritional and hydration status should be determined and corrected, if necessary, before surgery. Coexisting medical problems, particularly cardiac and pulmonary issues, should be well managed preoperatively.

Bowel Preparation

Each patient undergoes preoperative bowel preparation to minimize the potential risk of surgery if the use of any bowel is required. Even when ureterocystoplasty or other alternatives are planned, intraoperative findings may dictate the need for use of a bowel segment. Two days of a clear liquid diet before bowel preparation aid in clearing of solid stool. The patient should then undergo full mechanical bowel preparation the day before surgery. Such bowel preparations have usually been done in the hospital (O'Donnell, 2007); however, recent trends find this changing to an outpatient setting. A recent retrospective analysis showed a significantly shorter length of stay and lower median hospital cost for patients undergoing outpatient bowel preparation. In addition, the authors did not report an increase in postoperative complications (Weatherly et al., 2018). Major reconstructive procedures often require many hours of operative time with large fluid shifts. It is critical that the patient be well hydrated at the time of surgery even if it necessitates the use of intravenous fluids during the preoperative day. The use of oral antibiotics in bowel preparation, once dogma, is now a matter of personal preference. Special attention must be paid to the bowel preparation of patients with neurogenic dysfunction. Most of these patients have chronic constipation, and effective bowel cleansing can be difficult in such patients. Several days of oral cathartics at home may be helpful before formal preparation. Children with renal insufficiency should be observed carefully during bowel preparation for dehydration and electrolyte disturbances.

Theoretically, gastric contents are sterile, and administration of parenteral antibiotics or a routine bowel preparation is not necessary before gastrocystoplasty. Gundeti et al. (2006) suggested that routine bowel preparation may not be necessary before ileocystoplasty in children.

Urine Culture

All patients should have a urine culture performed several days before bladder reconstruction. Any patient with a positive preoperative urine culture should undergo treatment with either oral or intravesical antibiotics and have a second culture documenting sterile urine before the procedure. Many pediatric patients undergoing augmentation cystoplasty have spina bifida and a ventriculoperitoneal shunt. With a negative urine culture and good bowel preparation, the incidence of shunt infection or problems should be very low (Hayashi et al., 2008; Yerkes et al., 2001). In contrast, a recent report using the Pediatric Health Information System (PHIS) database showed an increase in shunt failures in patients undergoing bladder augmentation. The exact explanation for this association is unclear and likely multifactorial (Gonzalez et al., 2017).

Cystoscopy

Preoperative cystoscopy may be the final step in evaluating the native bladder, outflow, or ureteral orifices in pediatric patients. Endoscopy, if done, should be performed immediately before bladder reconstruction under the same anesthetic. Based on history, occasionally a patient may warrant endoscopic or radiographic gastrointestinal evaluation preoperatively.

Key Points: Evaluation and Preparation

- Evaluation for renal function, upper tract obstruction, and vesicoureteral reflux should be performed if hydronephrosis is present, although most such changes are secondary to the bladder dysfunction.
- Careful urodynamic evaluation is critical to understand all problems that may contribute to the dysfunction.
- The patient will likely require CIC to empty after reconstruction and must be capable of performing it on a reliable basis.
- Commitment of the patient and family is essential.
- Basic preoperative preparation includes sterile urine and thorough bowel cleansing.

Antireflux

Ureteral reimplantation into bladder, whether the ureter is dilated or not, is a standard procedure familiar to all pediatric urologists and reconstructive surgeons. The long-term success rate is good and complications rare. Such reimplantation is certainly preferable and usually possible during lower tract reconstruction. Special attention must be given to chronically scarred, short ureters sometimes found after urinary diversion. In Hendren's extensive experience with urinary undiversion (1998), most complications were related to those ureters.

Transureteroureterostomy and Single Ureteral Reimplant

Occasionally, the urinary bladder is so small that it is inadequate for bilateral reimplantation, and alternatives must be considered. It is preferable to reimplant both ureters separately, although **if the native urinary bladder is small and adequate for only a single ureteral tunnel, transureteroureterostomy (TUU) and a single reimplant may be helpful** (Fig. 37.1). Typically, the better ureter should be implanted into the bladder. The crossing ureter should be mobilized to swing gently across the abdomen to the recipient side in a smooth course without tension. It should be carefully mobilized with all of its adventitia and as much periureteral tissue as possible to preserve blood supply. Care must be taken not to angulate the crossing ureter immediately beneath the inferior mesenteric artery. The crossing ureter is widely anastomosed to the posteromedial aspect of the recipient ureter. The recipient is not mobilized or brought medially to meet the end of the other ureter. TUU, when fashioned appropriately, is successful and carries minimal risk for leakage or obstruction (Hendren and Hensle, 1980; Hodges, et al., 1963; Iwaszko et al., 2010; Mure et al., 2000; Noble et al., 1997). A history of previous calculi remains a relative contraindication to TUU.

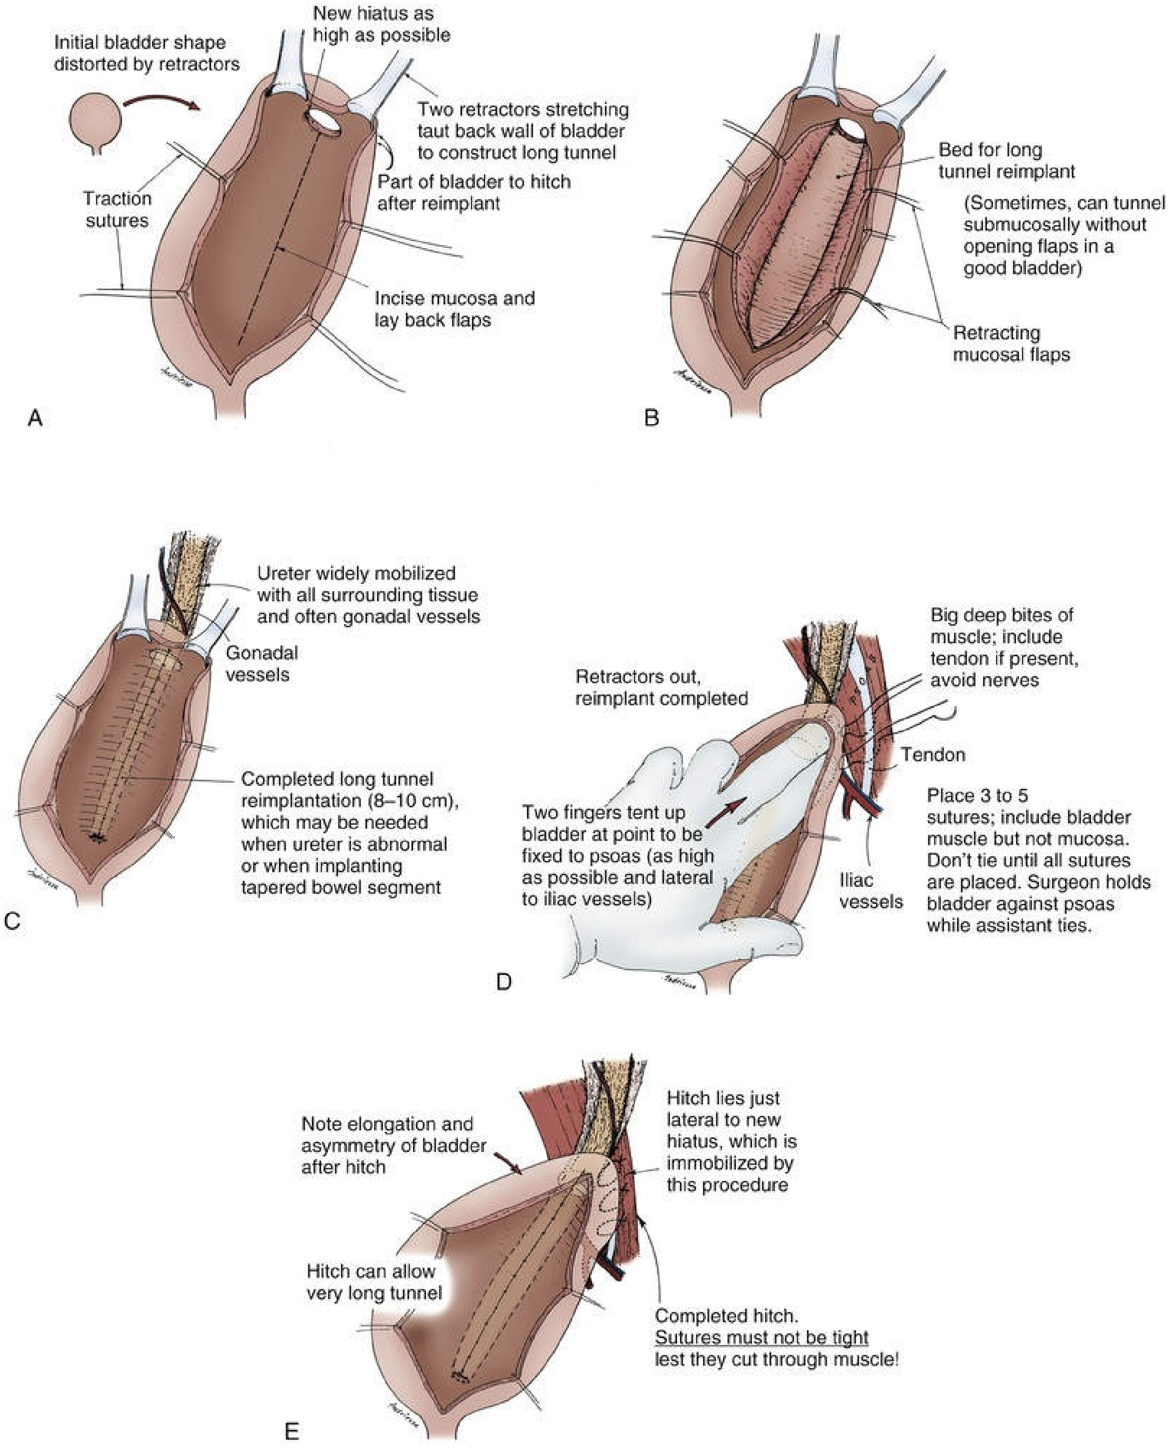
The manner in which the bladder is opened may optimize its use for a single reimplant. Rather than incising the bladder in the anterior midline, a wide, anterior U-shaped incision based cephalad can be made. This potentially elongates the bladder as a posterior plate that can be brought to one side or the other to meet a single ureter. For ureteral reimplantation after such an incision, a psoas hitch of the bladder fixes the bladder in position for a long, straight ureteral tunnel. Incision of the bladder in this way may also be useful in placing a continent catheterizable stoma to the umbilicus.

Psoas Hitch

Fixation of the bladder to the psoas muscle allows for precise control of the length and direction of a ureteral reimplant. A psoas hitch should prevent any angulation of the ureter with bladder filling. Such angulation may be particularly problematic or obstructive with a dilated and scarred ureter. The bladder should be secured to the psoas muscle and fascia using nonabsorbable sutures. Those sutures must not enter the bladder lumen or stones will occur. Broad, shallow purchases of the psoas muscle and fascia should be used to hold long term without trapping the sciatic nerve. The hitching sutures should not be tied so tightly that they cut through either bladder or psoas muscle. The contralateral bladder pedicle may be divided to increase bladder mobility and the length of the hitch on occasion. Although Hendren and Hensle (1980) suggested that the ureteral reimplant is more easily performed before the bladder hitch (Fig. 37.2), the steps should be performed in whichever order allows each to be done precisely with good visualization.



Initial bladder shape distorted by retractors
New hiatus as high as possible
Two retractors stretching taut back wall of bladder to construct long tunnel
Part of bladder to hitch after reimplant
Traction sutures
Incise mucosa and lay back flaps
A
Bed for long tunnel reimplant
(Sometimes, can tunnel submucosally without opening flaps in a good bladder)
Retracting mucosal flaps
B
Ureter widely mobilized with all surrounding tissue and often gonadal vessels
Gonadal vessels
Completed long tunnel reimplantation (8–10 cm), which may be needed when ureter is abnormal or when implanting tapered bowel segment
C
Big deep bites of muscle; include tendon if present, avoid nerves
Retractors out, reimplant completed
Tendon
Two fingers tent up bladder at point to be fixed to psoas (as high as possible and lateral to iliac vessels)
Iliac vessels
Place 3 to 5 sutures; include bladder muscle but not mucosa. Don't tie until all sutures are placed. Surgeon holds bladder against psoas while assistant ties.
D
Note elongation and asymmetry of bladder after hitch
Hitch lies just lateral to new hiatus, which is immobilized by this procedure
Hitch can allow very long tunnel
Completed hitch. Sutures must not be tight lest they cut through muscle!

FIG. 37.2 Technique for psoas hitch, which allows the construction of a long reimplantation tunnel and prevents angulation of the ureter or tapered bowel segment when the bladder fills. Monofilament nonabsorbable suture material is used to fix the bladder to psoas muscle. Care must be taken to avoid entering the bladder, which may cause stone formation on a suture. (Courtesy W. Hardy Hendren.)

Antireflux With Intestinal Segments

Necessity of ureteral reimplantation into an intestinal segment may occasionally determine the segment to be used for bladder augmentation or replacement. Long experience with ureterosigmoidostomy and colon conduit diversion has established an effective means of creating antireflux into a colonic segment; a flap valve mechanism can be created by tunneling the ureter beneath a tenia. Principles learned from ureterosigmoidostomy include a direct mucosal-to-mucosal anastomosis and a submucosal tunnel of adequate length. This technique has provided favorable long-term results since the 1950s (Goodwin et al., 1953; Leadbetter and Clarke, 1954; Nesbit, 1949) and is based on the initial work of Coffey (1911). Implantation may be done from within the reservoir or from without after the intestinal segment has been completely reconfigured and closed.

If a gastric segment is used for bladder augmentation or replacement, ureters may be reimplanted into the stomach in a manner remarkably similar to that used in the native bladder. The same principles for choosing the length of tunnel relative to the width of the ureter are used as with bladder. Creating an effective antireflux mechanism into an ileal segment is more difficult. The split nipple technique described by Griffith may prevent reflux at least at low reservoir pressure (Patil et al., 1976; Sagalowsky, 1995; Stone and MacDermott, 1989; Turner-Warwick and Ashken, 1967). A short longitudinal incision is made in the distal ureter, and the ureteral wall is turned back on itself. The nipple should be at least twice as long as the width of the ureter. The cuff is stabilized by suturing the ureter to itself. The adventitia of the ureter immediately proximal to the cuff is then approximated to the full thickness of the ileal wall at the hiatus so that the cuff protrudes into the lumen. Le Duc et al. (1987) described a technique in which the ureter is brought through a hiatus in the ileal wall. From that hiatus, the ileal mucosa is incised and the edges are mobilized to create a trough for the ureter. The spatulated ureter is laid into the trough and approximated to the mucosa at the distal end. The ileal mucosa is sutured to the lateral edges of the ureter and should eventually grow over it. Long-term results with these two techniques have been conflicting but in general have not proven as reliable as a tunneled ureterocolonic anastomosis in preventing reflux (Bihrle, 1997; Le Duc et al., 1987; Patil et al., 1976; Rowland, 1996), with one exception (Lugagne et al., 1997). It is also possible to create an antirefluxing, serosally lined tunnel between two limbs of ileum as described by Abol-Enein and Ghoneim (1999; Soygur et al., 2005).

Reinforced nipple valves of ileum have been used extensively for antireflux with the Kock pouch (Skinner et al., 1989). After several modifications by Skinner, good long-term results have been achieved. His technique requires a relatively long segment of ileum and use of permanent staples. Attempts have been made to secure the nipple long term without staples or mesh (Gosalbez and Gousse, 1998; Hanna and Bloiso, 1987; Tsuchiya et al., 2004). Maintenance of the intussuscepted cuff is the key to a successful result. The same forces that compress the nipple to achieve antireflux or continence tend to evert or destabilize it. An ileal nipple valve may be particularly useful with short, dilated ureters; an isoperistaltic segment of ileum may be left with the nipple to replace a short ureter. The antireflux mechanism is based on the ileal segment and not the ureter. In some neobladders, an isoperistaltic limb of ileum is positioned between the reservoir and ureters to discourage reflux, at least at low pressures (Studer and Zingg, 1997).

Key Points: Antireflux

- Ureteral reimplantation into native bladder is preferable when necessary; the initial bladder incision may facilitate such a procedure.
- An antireflux mechanism can be created with any bowel segment but is most challenging with ileum.

Bladder Neck Reconstruction

One of the greatest technical challenges facing the surgeon regarding bladder reconstruction is reliably providing adequate outflow resistance to achieve continence. The cause of bladder neck dysfunction may be neurogenic in origin or anatomic as noted with exstrophy, bilateral ectopic ureters, or ureteroceles. Each unique problem must be considered when addressing outlet resistance. Many operative techniques have been described for bladder neck reconstruction, indicating that no single option is best for all patients (Cole et al., 2003; Kryger et al., 2000; Lemelle et al., 2006). **Preoperative evaluation and thorough knowledge of the patient's specific physiologic limitations are required.**

The capability for a sustained bladder contraction to result in complete emptying by voiding or the absence of hyperreflexic contractions influences the technique selected for gaining outlet resistance. All operative techniques that create an increase in outlet resistance do so at the expense of detrusor contractibility. For reasons not clearly defined, increasing outlet resistance can result in a noncompliant hostile detrusor environment (Bauer et al., 1986; Burbige et al., 1987; Churchill et al., 1987). Provocative cystometry may uncover only some patients at risk, and close postoperative observation is mandatory (Kronner et al., 1998b).

Multiple techniques are available to tighten the bladder neck and include creation of a flap valve mechanism and placement of artificial or autologous bulking agents, slings, and the artificial urinary sphincter (AUS). **The selected option is individualized to the patient's pathologic process, needs, goals, and desire for independence.**

An important consideration is the patient's ability to empty well before reconstruction and the likelihood that he or she will be able to do so afterward. Many of the repairs prohibit spontaneous voiding. Some patients with neurogenic dysfunction require bladder augmentation and an increase in bladder outflow resistance, resulting in the need for CIC. Other diagnoses, especially when augmentation cystoplasty is not necessary, may allow for spontaneous voiding.

The following section covers operative techniques used to achieve urinary continence through bladder neck and external urinary sphincter reconstruction. Most of the results are based on experience in individuals with spinal dysraphism, but the techniques are used in children with other pathogenic conditions. All techniques have a learning curve that necessitates careful analysis of results and forthright reporting. An evidence-based review of operative bladder neck procedures found assessment of results to be limited by several factors, including the lack of a true, consistent definition of “success” and “continence,” consideration of patients with and without concomitant bladder augmentation, and consideration of small patient populations with mixed pathologic conditions (Joseph et al., 2003).

Young-Dees-Leadbetter Repair

The Young-Dees-Leadbetter bladder neck reconstruction is one of the most recognized operative techniques to increase outlet resistance. The original Young procedure has evolved and remains of primary consideration when reconstructing the exstrophic bladder neck (Ferrer et al., 2001).

Technique

Young's initial description (Young, 1919) of excising a portion of the bladder neck and tightening the bladder neck over a silver probe was modified by Dees (1949), who extended the length of excised tissue through the trigone. Leadbetter (1964) followed by elevating the ureters off the trigone and placing them in a more cephalad position on the bladder floor. This allowed for tubularization of the trigone and enhanced lengthening of the urethra. A detailed description and illustrations are found in the chapter on bladder exstrophy.

Results

Reports of success with the Young-Dees-Leadbetter bladder neck reconstruction in children with neurogenic sphincter dysfunction are limited, not only in the number of patients but also in overall improvement. Tanagho (1981) and Leadbetter (1985) independently reviewed their long-term results and showed minimal success in individuals with neurogenic dysfunction. They speculated that the outcomes were the result of a lack of muscle tone and activity in the wrapped muscle related to the underlying neurogenic problem. Many patients in the early series did not undergo bladder augmentation, possibly compromising the continence achieved. Contrary to the results reported in exstrophy patients, most individuals with neurogenic deficiency of the bladder neck require bladder augmentation and intermittent catheterization. Sidi et al. (1987b) documented a 4-hour continence interval in 7 of 11 patients after such repair, although 10 required catheterization and 9 augmentation. Of the 7 patients, 5 needed a second surgery to achieve continence. This small series is one of the more recent showing long-term results of the Young-Dees-Leadbetter reconstruction in children with neurogenic dysfunction; it has largely fallen out of favor. In an attempt to enhance the Young-Dees-Leadbetter procedure, Mitchell and Rink (1983) described the addition of external support and compression achieved through the placement of a silicone sheath around the reconstructed bladder neck. This was done to establish a plane for future placement of an artificial sphincter cuff, if necessary. The sheath improved the function of the repair by either increasing coaptation or maintaining the repair in a better anatomic position. Unfortunately, most of the thicker Silastic sheaths eventually eroded into the bladder or urethra (Kropp et al., 1993). Quimby et al. (1996) used a thinner Silastic sheath with interposed omentum and reported less risk of erosion. The authors noted improved continence and felt placement of an artificial sphincter cuff was easier when needed.

Donnahoo et al. (1999) reviewed one of the largest series of this repair used in neurogenic incontinence (38 children, 25 of whom were girls). A primary repair was performed in 24 children, a secondary procedure in 6, and a primary repair in conjunction with a silicone sheath in 8. Partial continence was achieved after the initial repair in 26 children (68%). All children with the silicone sheath were initially continent, but erosion occurred in 5. In addition, 35 (92%) of the children required augmentation cystoplasty to become continent without hostile detrusor characteristics. The authors found that, although continence could be achieved with this technique, it was at the expense of augmentation cystoplasty and multiple procedures. Their results are similar to those reported by Cole et al. (2003).

Fascial Sling

Sling procedures were developed in an attempt to increase resistance at the bladder neck. Artificial tissue and autologous fascia have been used. Continence is based on coaptation and elevation of the bladder neck that approximates opposing epithelial surfaces and increases outlet resistance greater above resting bladder pressure and the pressure reached during stressful activity or Valsalva behavior. With sling coaptation, the bladder neck remains fixed, and although a strong detrusor contraction can establish a voiding pressure leading to urinary flow, it rarely allows adequate bladder emptying in the face of anatomic or neurologic problems. The majority of pediatric patients who undergo a sling procedure must be prepared for CIC. The resistance achieved with bladder neck slings can potentially be overcome by overactive bladder contractions or elevated pressure caused by diminished bladder compliance. Therefore simultaneous bladder augmentation has again been reported in 55% to 100% of patients who achieve urinary continence after a sling procedure (Bauer et al., 1989; Bugg and Joseph, 2003; Elder, 1990; Cole et al., 2003; Decter, 1993; Dik et al., 1999; Dik et al., 2003; Godbole and Mackinnon, 2004; Kakizaki et al., 1995; Perez et al., 1996a; Walker et al., 2000). Only Snodgrass et al. have reported good results of bladder neck reconstruction without augmentation cystoplasty in these patients (Snodgrass et al., 2007, 2010; Snodgrass and Barber, 2010). Furthermore, this group found that 35% of children with sustained pressures of more than 40 cm H_2O on anticholinergic therapy for more than 1 year developed either reflux or hydronephrosis at a mean of 23 months. These upper tract changes resolved with a combination of overnight catheter drainage and the addition of intravesical anticholinergic and Deflux. Only one patient was augmented, and the authors concluded that end filling pressures of more than 40 cm should not be used as criteria for augmentation after bladder neck procedure alone (Snodgrass et al., 2014). Long-term assessment from 2000 to 2014 of 109 patients from this same patient population found that 70% required an additional continence procedure, 30% have required augmentation, 50% developed upper tract changes, and 20% developed chronic kidney disease (Grimsby et al., 2015). Alternatives to fascia, such as an expanded fluorocarbon polymer (Gore-Tex) have been used in a similar fashion, although early continence has not been maintained (Godbole and Mackinnon, 2004). Good early results have been noted with some biodegradable scaffolds (Colvert et al., 2002).

Technique

The bladder neck is exposed by clearing fatty tissue overlying the bladder neck and the lateral endopelvic fascia. An incision is made within the endopelvic fascia for approximately 2 cm. The junction between the bladder neck and proximal urethra can be identified by placing a transurethral catheter into the bladder and gently pulling down on the catheter to lodge the balloon at the bladder neck. Using blunt dissection, a plane between the posterior bladder neck and vagina in girls or rectal wall in boys is developed. The proper plane may be more easily developed from the cul-de-sac by dissecting behind the bladder and ureters from above (Badiola et al., 2000; Lottmann et al., 1999). If the landmarks are not easily defined, as in a secondary repair, the dissection becomes difficult. It may be appropriate to open the bladder to help prevent inadvertent dissection into the urethra or posterior structures. Dik et al. (2003) proposed use of a transvaginal approach, eliminating the need to open the bladder or dissect between the bladder neck and anterior vagina.

When fascial tissue is used, the technique is based on that described by McGuire and Lytton (1978) for stress urinary incontinence. Rectus abdominus fascia 1 cm in width and of an appropriate length is harvested. This fascia can be taken either in vertical or horizontal fashion depending on the initial skin incision. Fascia from other sites has been used in a similar fashion but requires a second incision. Cadaveric tissue or biodegradable scaffolds may also be used (Albouy et al., 2007; Colvert et al., 2002; Misseri et al., 2005). All are usually secured to the anterior rectus fascia on either side. Autologous fascial tissue has been used combining the benefits of a compressive wrap and suspension of the proximal urethra and bladder neck. Several variations of fascial placement and configuration have been described (Bugg and Joseph, 2003; Dik et al., 2003; Elder, 1990; McGuire et al., 1986; Perez et al., 1996a; Woodside and Borden, 1982). When fascial slings and wraps are used for neurogenic sphincter incontinence, there is not as much concern for creating a wrap or sling that is too tight because most patients are preferentially managed with CIC. Placement of a bladder neck sling using laparoscopic and robotic assistance is currently being explored by minimally invasive surgeons (Bagrodia and Gargollo, 2011; Mattioli et al., 2010; Storm et al., 2008). In a small retrospective study, although the robotic approach took significantly longer to perform, there did not appear to be differences in overall complication rate, length of stay, and number of additional procedures required (Grimsby et al., 2016). The length of operative time may be a reflection of the overall learning curve, whereas magnification and access to the bladder neck in the deep pelvis appear to aid in the dissection and placement.

Results

Fascial slings have been used more extensively and with better results in girls with neurogenic sphincter incompetence, although recently some success has been reported in boys. Overall, long-term success with fascial slings in the neurogenic population has varied greatly from 40% to 100% (Kryger et al., 2000). A variation thought to contribute to a higher success includes a circumferential fascia wrap around the bladder neck. A circumferential wrap may equalize the compressive pressure over a greater surface area of bladder neck and posterior urethra (Strang et al., 2006; Walker et al., 1995). With the wrap, simultaneous suspension has also been used (Bugg and Joseph, 2003). Success rates have varied so much that it is difficult to determine whether any modification of the sling accounts for an increase in continence. Most patients who have undergone a fascial sling or wrap have also had simultaneous bladder augmentation. **Success of the sling, as with most repairs, apparently is improved with augmentation cystoplasty in this patient population by almost all reports** (Castellan et al., 2005). Perez et al. (1996a) reviewed the outcome of sling cystourethropexy in 39 children, 15 of whom were boys; 1 of 4 various techniques was performed. In evaluation of postoperative continence based on age, sex, underlying diagnosis, preoperative urodynamics, surgical technique, and enterocystoplasty, only concomitant enterocystoplasty was predictive of a successful outcome. This was not the experience of Snodgrass, who reported successful outcome of bladder neck sling without the need for enterocystoplasty. Snodgrass et al. (2010) reported manageable bladder hostility in their determination, but no need for augmentation, in 26 patients who underwent a sling only. They achieved continence in 46% of 35 patients undergoing a sling alone and 82% of 17 patients undergoing a sling combined with a Leadbetter-Mitchell bladder neck repair (Snodgrass and Barber, 2010).

Unlike with the Silastic sheath, erosion rarely occurs with fascial slings. Gormley et al. (1994) reported a revision rate with fascial slings of 15%. Placement of a fascial sling does not eliminate the possibility of later placement of an AUS (Barthold et al., 1999; Decter, 1993). It is not unreasonable to consider placing a fascial sling in a child with a marginally competent bladder neck and deficient external sphincter if the child is undergoing augmentation cystoplasty and already requires intermittent catheterization.

Bladder Neck Bulking Agents

Vorstman et al. (1985) reported one of the initial descriptions of injection therapy with a bulking agent into the bladder neck of incontinent children. The initial enthusiasm for use of polytetrafluoroethylene was quickly tempered because of concern over migration of particles to regional and distant sites including pelvic nodes, lungs, brain, kidney, and spleen found in animal models (Malizia et al., 1984). The technique remains of interest, and several alternatives to polytetrafluoroethylene have been assessed, including glutaraldehyde cross-linked collagen, dextranomer/hyaluronic acid copolymer, and polydimethylsiloxane (Alova et al., 2012a; Dean et al., 2007; Guys et al., 2006; Knudson et al., 2006; Leonard et al., 1990a; Lottmann et al., 2006). Bovine collagen should not be used in latex-sensitive children with spina bifida because the product is not latex free (Kryger et al., 2000). In an attempt to achieve an ideal substance for injection, investigation is ongoing using autologous cartilage cells harvested from a separate site then grown in an alginate matrix for endoscopic implantation (Bent et al., 2000). Preliminary results show a positive effect in women with stress incontinence. Whether this or other materials are appropriate alternatives for neurogenic sphincter incontinence in children is unknown.

To alleviate the risks of injecting a foreign biologic product, alternatives to collagen and bovine have been investigated. Polydimethylsiloxane is one such agent. It is composed of sterile solid textured silicone particles, with an average size of 200 µg, suspended in a biologic hydrogen carrier. The large size of the particles should almost eliminate lymphatic and distant migration (Beisang and Ersek, 1992; Guys et al., 1999; Guys et al., 2006; Halachmi et al., 2004). Contemporary reports favor the use of dextranomer/hyaluronic acid (Alova et al., 2012a; Dean et al., 2007; Dyer et al., 2007; Kaye et al., 2010; Kitchens et al., 2007; Lottmann et al., 2006).

Technique

Endoscopic exposure is used for localizing the proximal urethra and bladder neck. Injection can be done directly through the working channel of the endoscope, often one with an offset lens system. Ideal placement of the material is in a subepithelial space, mobilizing the epithelium toward the lumen of the bladder neck. When completed in a circumferential fashion, adequate epithelial coaptation may occur, which can raise outlet resistance. Alternatively, periurethral injection in women through a long needle placed from the perineum or via a suprapubic approach has been used. Dean et al. (2007) advocate a combined antegrade and retrograde approach. Evidence is lacking regarding whether the exact approach affects success, but accurate placement is important and transurethral injection is usually preferred.

Results

The durability and success of bladder neck and proximal urethral injection remain in doubt for the pediatric population, particularly those with neurogenic dysfunction. True continence, as defined by a 4-hour dry period between voidings or catheterizations, has been reported to be at most 78% and has ranged as low as 5% (Alova et al., 2012a; Bomalaski et al., 1996; Capozza et al., 1995; DaJusta et al., 2013; Dean et al., 2007; De Vocht et al., 2010; Godbole et al., 2003; Guys et al., 2001; Halachmi et al., 2004; Kaye et al., 2010; Kitchens et al., 2007; Leonard et al., 1990a; Perez et al., 1996b; Silveri et al., 1998; Sundaram et al., 1997). Several factors play a role in the outcome, one of which is a history of any previous operative bladder neck repair. Success is enhanced by elevation of the epithelium of the bladder neck, which may be compromised by scarring from previous operative procedures. **The concept of a minimally invasive operation used to enhance a marginal result gained from a more formal bladder neck repair is enticing; unfortunately, the data are lacking to show that bladder neck injection is of lasting value or that repeat treatments are warranted in that setting** (Alova et al., 2012a; DaJusta et al., 2013; De Vocht et al., 2010).

Sundaram et al. (1997) reported on the efficacy and durability of glutaraldehyde cross-linked bovine collagen in 20 children, 12 of whom had neurogenic sphincter dysfunction. More than half of the children required two or three independent injections. Success was achieved in only 1 patient (5%) who was considered dry; 5 had some improvement, and 10 had either no change or transient improvement for only 2 to 90 days. In the hands of these researchers, collagen therapy only delayed the ultimate need for bladder neck reconstruction. Submucosal bladder neck injection of bovine dermal collagen was used by Perez et al. (1996b) in 32 patients. Continence was achieved after a single injection in only 20% of the children with neurogenic dysfunction. The authors concluded that even though their success was limited, the low morbidity and ease of placement justified a trial of submucosal injection in selected children.

Guys et al. (2006) treated 49 children with polydimethylsiloxane, 41 of whom had neurogenic bladder neck and sphincter incontinence. The level of continence deteriorated through 18 months after the procedure then stabilized. After an average follow-up of 73 months, success had been achieved in 16 (33%), and 7 (14%) were improved. Godbole et al. (2003), Halachmi et al. (2004), and Dyer et al. (2007) independently came to the conclusion that regardless of the material injected (polytetrafluoroethylene, collagen, polydimethylsiloxane, dextranomer/hyaluronic acid), short-term success is not long lasting. Alova et al. (2012b) determined that failure after 1 year using dextranomer and hyaluronic acid was primarily caused by neurogenic bladder dysfunction and deterioration.

However, failure after injection therapy does not preclude a successful outcome when it is salvaged by more invasive measures (Alova et al., 2012b).

The cost of the bulking agents can be excessive, and there does not appear to be any financial benefit over a formal repair (Kryger et al., 2000). **At present, bulking agents play a limited role for increasing outlet resistance and should be reserved for a select group of patients. The exact criteria that define that group have not been well established.** Patients with marginal native outflow resistance are probably better candidates than those with minimal preoperative function.

Artificial Urinary Sphincter

The AUS has been recognized as a device that can result in prompt continence in select children while preserving their ability to void spontaneously. The AUS was introduced by Scott et al. (1974). The general concept and design of the initial model have been retained; however, improvements and enhancements have evolved that have a positive impact on the long-term success of the AUS. The current AS800 model includes a seamless, pressurized balloon reservoir, nonkink tubing, and changes in the cuff that facilitate its placement and effectiveness with coaptation of the bladder neck and proximal urethra (Barrett et al., 1993; Catti et al., 2008; Lai et al., 2007; Light and Reynolds, 1992; Ruiz et al., 2006). Alternatives to the AS800 model have also been explored (de O Vilar et al., 2004; Farrugia et al., 2012).

Technique

Placement of the cuff should be at the level of the bladder neck in all females and prepubertal boys. It is also the most desirable and effective location in pubertal and adult males with neurogenic sphincter incompetence. The bulbar urethra can be used as an alternative site in men with mature spongiosum. Levesque et al. (1996) have indicated that age is not a factor regarding placement of the cuff around the bladder neck. They found that children do not outgrow the AUS as they progress through puberty and that replacement of the cuff is not routinely necessary. The AUS cuff can be positioned around intestinal segments used in total urinary reconstruction but is more prone to erosion there. Several authors have described the successful placement of the cuff around a bowel segment, particularly when omentum is interposed between the cuff and the segment (Burbige et al., 1987; Light et al., 1995; Weston et al., 1991).

Placement of an AUS in children is the same as that described for adults. Development of the proper plane for the cuff is virtually identical to that described for a fascial sling. The cuff should be sized snugly, but not tightly, around the bladder neck. Obviously a sterile environment is critical when considering placement of the AUS to avoid infection. For that reason, preoperative antibiotics are a necessity, and confirmation of sterile urine required. With those precautions, there is freedom to open the bladder when dissecting around the bladder neck. This often facilitates the dissection and ensures proper placement. The AS800 model has a locking mechanism in the pump that permits the AUS to be deactivated and activated without a second operative procedure. Experience has shown that leaving the unit deactivated with the cuff deflated after placement allows formation of a pseudocapsule around the cuff and decreases the risk of erosion (Furlow, 1981; Hanna, 1981; Sidi et al., 1984). The noncycled AUS occasionally may provide enough resistance for continence, eliminating the disadvantages of activation (Herndon et al., 2004).

Results

There are substantial short- and long-term data regarding continence after placement of the AUS; the largest series was presented by Herndon et al. (2004). **In investigation of continence, it must be placed in context of the cost experienced by the patient, defined by mechanical malfunctions resulting in secondary operative procedures and more catastrophic complications such as device infection or erosion.** Dramatic improvement regarding the need for secondary procedures has occurred because of the technical refinements in the device. Ten- to 15-year long-term follow-up of the AUS in children has been reported (Castera et al., 2001; Hafez et al., 2002; Herndon et al., 2003; Kryger et al., 1999; Kryger et al., 2001; Levesque et al., 1996; López Pereira et al., 2006; Ruiz et al., 2006). All groups report an impressive continence rate of 80% and a functioning sphincter in 95% of patients. Herndon et al. (2003) present the most comprehensive long-term data. They achieved overall continence in 86% of 142 patients with an average follow-up of 10 years. Age at implementation does not appear to affect continence (Kryger et al., 2001).

Although the AUS is one of the few surgically created continence mechanisms that does not negatively affect spontaneous voiding, CIC remains an important adjunct in approximately 75% of children with neurogenic sphincter incompetence and can be performed successfully through the cuff (Castera et al., 2001; Catti et al., 2008; Diokno and Sonda, 1981; Gonzalez et al., 1995; Hafez et al, 2002; Herndon et al., 2003; Kryger et al., 1999; Kryger et al., 2001; Levesque et al., 1996; Ruiz et al., 2006).

Herndon et al. (2003) reported device malfunction with 64% of the pre-AS800 model and 30% with the AS800. Sphincter erosion was similar for the pre-AS800 and AS800, occurring at 19% and 16%, respectively, in their experience, similar to the reports of others (Bauer, 2008; Ruiz et al., 2006). Fastidious attention to detail and sterile technique diminish the risk of infection but do not eliminate it. When infection occurs without erosion, the unit can be removed and later replaced (Nurse and Mundy, 1988). Infections are minimized by sterilizing the urine preoperatively, meticulously cleaning the wound site, using a preoperative bowel preparation, administering perioperative parenteral antibiotics, and performing copious antibiotic wound irrigation. Newer cuff design and a 6-week delay in activation of the device help formation of a thickened pseudocapsule that substantially decreases bladder neck and proximal urethral erosion. Kryger et al. (1999) indicated that erosion can be virtually eliminated when the cuff is placed as the primary treatment for bladder neck incompetence.

Upper urinary tract changes including hydronephrosis have been reported to occur in up to 15% of children after placement of the AUS (Churchill et al., 1987; Gonzalez et al., 1995; Kryger et al., 1999; Levesque et al., 1996; Light and Pietro, 1986). In extreme cases, renal insufficiency has resulted. **It is now recognized that occlusion of the bladder neck in children with neurogenic sphincter incompetence can result in the unmasking or development of detrusor hostility manifesting with a decrease in bladder compliance or increase in detrusor overactivity** (Bauer, 2008; Bauer et al., 1986). **Careful preoperative urodynamic assessment helps to identify only some of the children who are at risk** (Dave et al., 2008; Kronner et al., 1998b). When hostile bladder characteristics are found preoperatively, anticholinergic medications can be beneficial for hyperreflexic contractions, but augmentation cystoplasty is usually required for diminished compliance. Churchill et al. (1987) showed that favorable parameters can be maintained after placement of the AUS; however, close observation is still recommended in any child undergoing bladder neck reconstruction to identify any early deterioration in bladder dynamics before upper tract changes.

Some children undergoing sphincter placement need bladder augmentation as well, and the timing of the two procedures may be questioned because of the concern for AUS infection. Light et al. (1995) reported a 50% infection rate with simultaneous augmentation compared with 9.5% when the procedures were staged. To the contrary, a contemporary review by Miller et al. (1998) found infection necessitating removal of the device occurred in only 2 of 29 such patients (7%). This low rate is similar to that noted by others (Gonzalez et al., 1989; Strawbridge et al., 1989). Although infection of the AUS is a concern, placement can be successfully undertaken when bowel is simultaneously used for total continent reconstruction of the bladder and bowel (Bar-Yosef et al., 2011).

The ultimate benefits of the AUS lie in its ability to achieve a high rate of continence while maintaining the potential for spontaneous voiding. For practical purposes, when intermittent catheterization is required along with augmentation cystoplasty, use of native tissue for continence eliminates the long-term concern for infection or erosion and the risk of mechanical failure.

Urethral Lengthening

Young's original description of bladder neck reconstruction (1919) consisted of two components: excision of a segment of anterior urethral bladder neck tissue and narrowing of the adjacent remaining posterior portion. However, this ultimately led to failure because the tubularized segment remained unsupported within the bladder. Refinements by Dees (1949) and Leadbetter (1964) maximized good muscle tone at the bladder neck and extension of the urethral tube through the trigone.

Tanagho (1981) described a cephalad-based anterior detrusor wall tube. Closure of the tubularized bladder neck created circularly oriented muscle fibers, which Tanagho described as a sphincter mechanism. However, he cautioned against the use of this technique in the neurogenic population. Because of potential breakdown of that tubularized bladder neck and poor results, other techniques have been developed based on the concept of a flap valve mechanism for urinary retention. Kropp and Angwafo (1986) described urethral lengthening and creation of a flap valve for neurogenic bladder neck and sphincter dysfunction. The technique is based on an anterior detrusor wall tube that is kept in continuity with the urethra, tubularized, and implanted into a submucosal tunnel within the trigone. Conceptually this is effective; however, difficulty with catheterization is a common problem and significant concern.

Technique

A Foley catheter is placed intravesically and the bladder filled to capacity. The bladder is exposed through either a midline or low transverse abdominal incision. The bladder neck is then identified with application of gentle catheter traction. A 6- × 2-cm rectangular flap based on the bladder neck and urethra is then isolated. Stay sutures are placed, and the flap is mobilized in continuity with the proximal urethra. The detrusor musculature at the bladder neck is divided, separating the bladder and urethra, or the muscle may be left intact at the 5 and 7 o'clock positions. In girls, the anterior vaginal wall is exposed; in boys, the seminal vesicles. The rectangular strip based on the urethra is tubularized posteriorly around the urethral catheter with a continuous absorbable suture. The distal portion of the tubularized strip should be approximated in an interrupted fashion to facilitate excision of excessive tissue without jeopardizing the suture line. A capacious submucosal tunnel through the trigone is then created posteriorly for the neourethra (Fig. 37.3). A wide tunnel is required to prevent kinking at the level of the bladder neck, which would impede catheterization. It is important to eliminate dead space at the entrance of the urethra into the bladder; this can be accomplished by placing lateral anchoring sutures in the region of the bladder neck. The detrusor tube must be pulled straight through the tunnel without curve or deviation to facilitate catheterization. Waters et al. (1997) and Kropp (1999) have not found it necessary to reimplant all ureters in a cephalic location; they now typically reimplant only refluxing ureters (Kropp, 1999). When closing the bladder, the lateral wings in the region of the bladder neck are approximated and incorporate adventitia of the tubularized urethra. This enhances a watertight closure and is continued for 2 to 3 cm anteriorly, often up to the area of augmentation. The tubularized neourethra should be long enough to reach the true lumen of the bladder, where it is exposed to pressure as an effective flap valve.

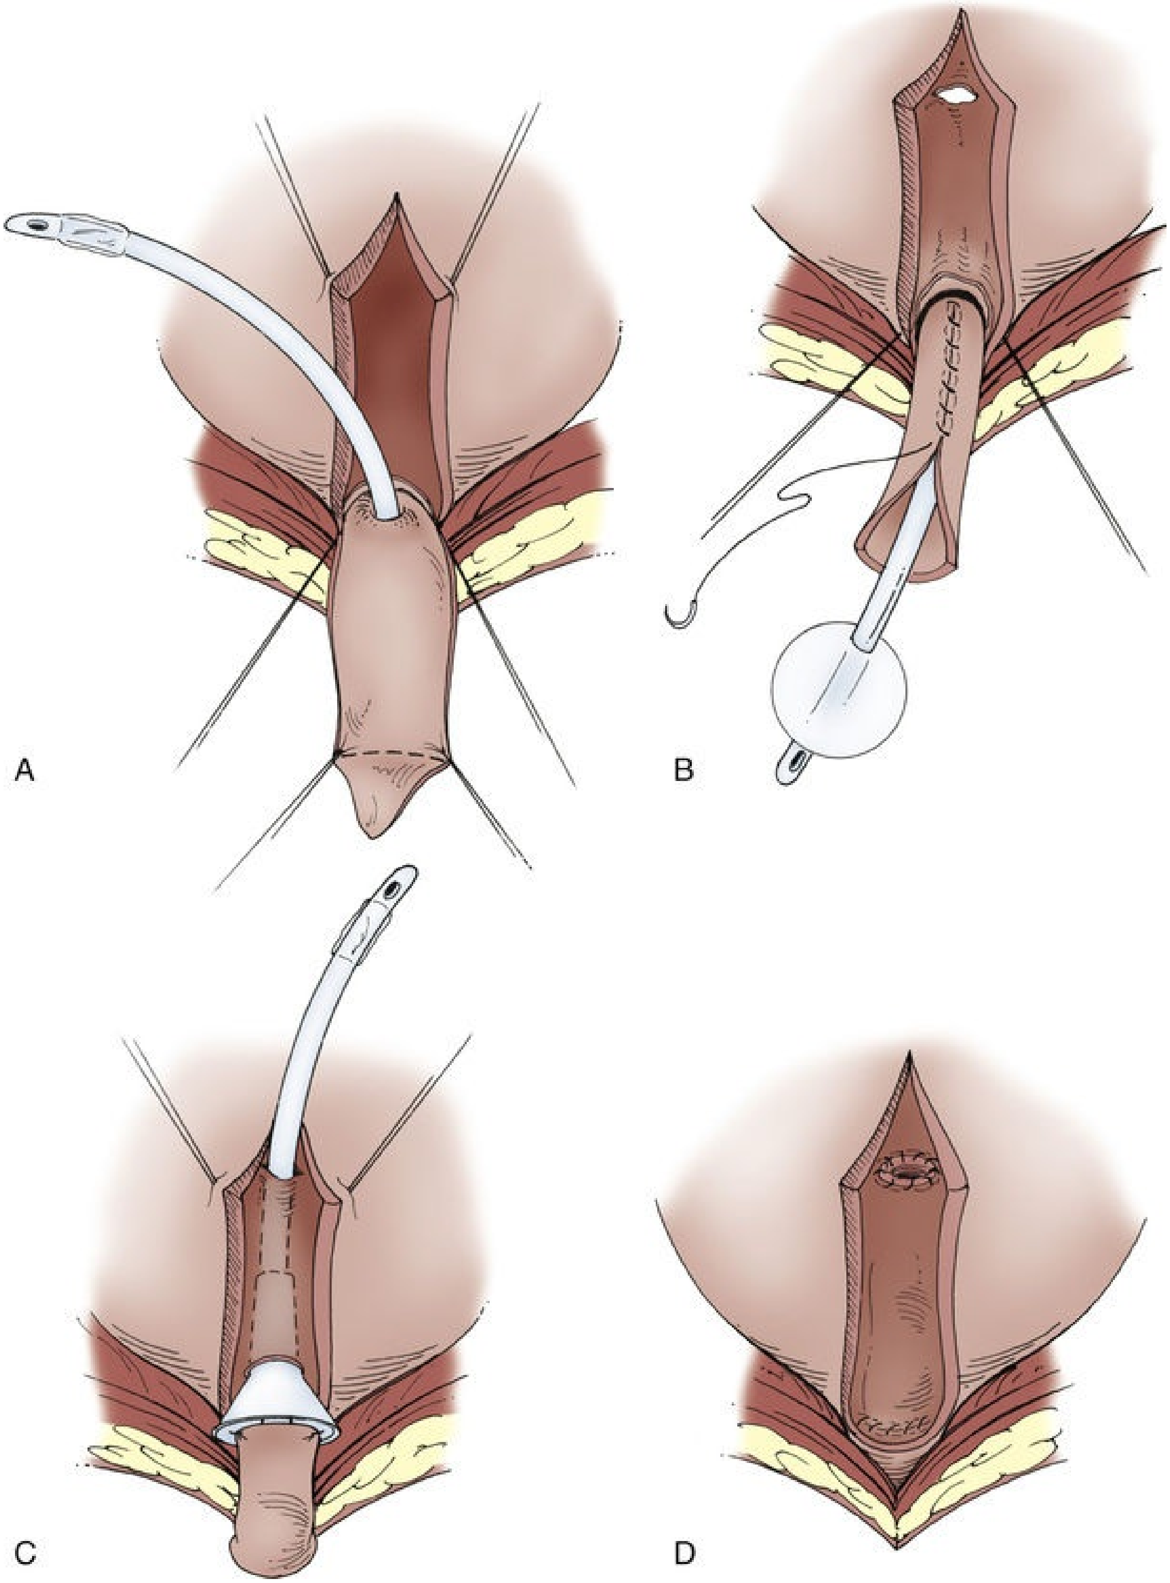

FIG. 37.3 Kropp anterior detrusor tube. (A) An anterior flap of bladder (2 cm wide × 5 to 6 cm long) is developed in continuity with the urethra. (B) The anterior flap is tubularized over a catheter. A tunnel beneath the mucosa of the trigone is made between the ureteral orifices for the length

of the tube. (C) The tubularized flap is brought through the tunnel. (D) The detrusor tube is secured to the floor of the trigone with interrupted absorbable suture in a straight course.

Because of the difficulties with catheterization, modifications of the Kropp bladder neck procedure have been described. Belman and Kaplan (1989) suggested a simplified approach. They harvested a rectangular strip from the anterior bladder wall similar to that described by Kropp. The lateral and posterior musculature at the bladder wall, however, is not incised, and the proximal urethra and bladder are not separated. The flap is tubularized over an 8-Fr catheter. The epithelium on the floor of the bladder is incised contrary to the tunnel made by Kropp. The tube is placed within the trough with the proximal meatus secured on the floor of the bladder. The epithelial edges of the trough are then secured to the lateral aspect of the tube. As with the initial description, the suture line for tubularization of the urethra lies posteriorly against trigonal muscle. Closure of the bladder begins with reapproximation of the lateral walls of the bladder to the tube until the bladder edges meet. The remaining portion of the bladder is covered by an augmentation. Regardless of any modification to the Kropp bladder neck procedure, catheterization potentially remains problematic, and therefore the patient should be prepared for a catheterizable abdominal-vesicle channel.

An innovative trial by Chrzan et al. (2013) was undertaken in 18 patients, using laparoscopic techniques that allowed for “vesicoscopic” exposure of the bladder neck. Chrzan et al. were able to lengthen the urethra by creating a U incision around the bladder neck and onto the epithelial surface of the bladder dome. This prevented interference of the ureteral orifices and could be undertaken in patients in whom other bladder neck procedures had failed. Unfortunately, a long-term benefit has not been achieved.

Results

Snodgrass (1997) examined the results in 23 children, 22 of whom had neurogenic sphincter incompetence, and noted continence in more than 90% of the children. The most common complication was difficult catheterization, particularly in boys. Less than half of the boys in Snodgrass's series catheterized through the native urethra; the majority did so via an abdominal wall stoma. Postoperative vesicoureteral reflux was identified in 9 of 18 children, and Snodgrass speculated this was because of lateral retraction of the ureters. Their recommendation was made to leave the posterior bladder wall open and flat when receiving the augmentation to prevent this distortion. Kropp (1999) has not had as much difficulty with catheterizations in his patients and likewise has achieved a high rate of continence without a high incidence of new reflux.

Some patients with an effective flap valve mechanism created by urethral lengthening never leak per urethra. This potentially puts them at risk for upper tract deterioration or bladder rupture, particularly if they do not or cannot catheterize reliably. Snodgrass (1997) thought his modification was beneficial in that it resulted in a shorter intravesical tunnel for the neourethra, allowing for leakage per urethra with overfilling.

Pippi Salle Procedure

In an attempt to maximize the benefits of the Kropp technique and decrease problems with catheterization, Salle et al. (1994) **reported an anterior bladder onlay flap.** With this technique, the posterior wall of the neourethra is intact, theoretically providing less potential hang-up during catheterization. Since the first report, modifications have been made to improve flap viability, minimize fistula formation, and extend the indications for the procedure beyond that of the neurogenic bladder (Salle et al., 1997).

Technique

An anterior, full-thickness bladder wall flap 5 × 1 cm is mobilized to the bladder neck with 0.1 cm of its epithelial edges excised to avoid overlapping suture lines. Two parallel incisions down to the level of the muscle are made in the mucosa of the trigone from the native bladder neck. The anterior flap is secured to the midline strip of trigone mucosa to create a tube or lengthened urethra using absorbable suture. The muscle on either side of the posterior epithelial strip may be incised superficially to provide an edge to which the muscle of the anterior flap may be approximated with a second layer of suture in an effort to avoid fistula (Fig. 37.4). The more lateral mucosa of the trigone is mobilized and closed over the midline urethra. Distally, the muscle of the bladder neck is wrapped tightly around the urethra with closure. Proximally, the lengthened urethra should extend well into the lumen of the bladder.

FIG. 37.4 Pippi-Salle anterior detrusor tube onlay. (A) An anterior detrusor tube (1 cm × 4 to 5 cm) is mobilized to the level of the bladder neck. (B) A central strip on the floor of the bladder is developed by incision of the epithelium on either side. (C) The anterior detrusor flap is secured to the strip in a two-layer fashion, approximating the epithelium with the first layer and muscle with the second. (D) The lateral mucosa of the trigone is mobilized and secured over the lengthened urethra. Distally, the bladder is closed to itself and should incorporate a portion of the anterior detrusor flap to ensure a watertight seal. (E) After distal closure the remaining portion of the bladder is left open if augmentation cystoplasty is necessary.

Results

Initial complications of this procedure included persistent incontinence, urethrovesical fistula, and partial necrosis of the intravesical neourethra. Widening the base of the urethra at the level of the bladder neck may minimize these problems. Children who have previously undergone bladder surgery can have a secondary Salle repair if the anterior bladder flap is lateralized slightly to avoid any old midline suture line.

Salle et al. (1997) found that continence was achieved in 12 of 17 patients (71%) for more than 4 hours. Catheterization difficulties occurred in only 3 of 17 children, 1 of whom subsequently underwent an appendicovesicostomy. Fistula formation at the base of the flap between the proximal, intravesical urethra and bladder occurred in 2 children and resulted in recurrent incontinence. This problem appears to be diminished by creating a wider base to the flap and generously trimming the epithelial edges there. Jawaheer and Rangecroft (1999) reported a diurnal continence rate of 61% for 3 or more hours with the Salle procedure. However, only 44% of their patients were dry through the night. Less trouble with catheterization has occurred relative to the Kropp technique and rarely remains a problem. Continence rates have not been as high in most series (Cole et al., 2003; Mouriquand et al., 1995; Rink et al., 1994).

Canales et al. (2006) used a miniature intravesical lengthening of shorter length (3 cm) and radius (8 Fr) with the intent of enhancing resistance, minimizing the use of bladder, and avoiding need for ureteral reimplantation. After 2½ years of follow-up, 8 of 9 children were continent and had an average leak point pressure of 71 cm H_2O. A recent comparison between the Kropp and Pippe-Salle procedures showed similar dry intervals without the need for additional bladder neck procedure. However, the rate of delayed augmentation was high for both groups who did not have a concomitant augment at the time of bladder neck procedure. In addition, both procedures were associated with a high rate of secondary surgeries unrelated to the bladder neck (Szymanski KM et al., 2016).

Bladder Neck Division

The ultimate procedure to increase bladder outlet resistance is to divide the bladder neck so that it is no longer in continuity with the urethra. It must be accompanied by creation of a continent abdominal wall stoma and should be performed only in patients who will reliably catheterize. If effective, it prevents any leakage or pop-off per urethra and increases the risk for upper tract deterioration or bladder rupture if emptying is not performed. Division is seldom performed as a primary procedure but may be considered if the previously mentioned repairs fail (Baradaran et al., 2012; Bergman et al., 2006; De Troyer et al., 2011; Kavanagh et al., 2012; Khoury et al., 1999; Landau et al., 2009).

Closing the bladder neck moves the reconstructive effort into the realm of continent urinary diversion. The bladder neck is abandoned from a physiologic standpoint, although the bladder may be used as part of the reservoir. Effective division of the bladder neck is not a simple procedure. The bladder must be aggressively mobilized away from the urethra. The bladder should be closed distally in several layers after the posterior lip of bladder neck and trigone are rolled anteriorly and widely separated from the distal urethra. Omentum has usually been interposed, as has rectus abdominus muscle (Smith et al., 2010). Without these steps, fistulization and leakage per urethra can occur (Khoury et al., 1999; Nguyen and Baskin, 2003). With aggressive mobilization, the fistula rate can be low (Thomasch et al., 2009). Although eliminating secondary access to the bladder creates a concern, long-term follow-up indicates that a successful outcome is achieved in almost all patients (De Troyer et al., 2011; Kavanagh et al., 2012; Landau et al., 2009).

Key Points: Bladder Neck Reconstruction

- Any repair other than placement of an AUS, particularly if combined with cystoplasty, is likely to make spontaneous voiding inadequate.
- Young-Dees-Leadbetter repair in the spina bifida population has variable

success related to the underlying neurogenic dysfunction.

- Fascial slings have been used more extensively and with better results in girls than boys with neurogenic dysfunction, although those results vary widely.
- Experience does not yet suggest that injection of bladder neck bulking agents has a lasting effect on severe neurogenic sphincter incompetence.
- A functioning, well-positioned artificial sphincter provides good resistance and is best reserved for patients who can empty adequately with spontaneous voiding.
- Urethral lengthening procedures use a flap valve mechanism for continence that disrupts any chance of voiding and may make catheterization per urethra difficult.
- The success of most bladder neck repairs in the neurogenic population improves if combined with augmentation cystoplasty.
- Bladder neck repair may unmask or result in new bladder hostility; careful follow-up is mandatory.

Bladder Reconstruction

Cutaneous Vesicostomy

Cutaneous vesicostomy is used to “vent” the bladder, thus minimizing the effect of high intravesical pressures to the upper tracts. This technique is an excellent temporary or permanent diversion in patients with worsening upper tract dilation, recurrent febrile UTIs with high grade reflux, and a high pressure bladder despite maximal medical therapy (Donmez et al., 2017). Vesicostomy is typically used in young patients and has proven to be a safe alternative until definitive reconstruction can take place. Disadvantages include stenosis, prolapse, and incontinence (which can be difficult to manage as children get older).

Augmentation Cystoplasty

The initial approach to the patient for augmentation cystoplasty is similar regardless of the bowel segment to be used. Cystoscopy may be performed preoperatively to identify any unsuspected anatomic abnormalities that may affect the surgery or postoperative care. If other bladder procedures such as ureteral reimplantation are to be performed, the bladder is left full after cystoscopy. If not, the bladder is emptied to allow easy access to the peritoneal cavity.

As a general rule, a midline incision is preferred for intestinal cystoplasty, although these procedures can be performed through a lower transverse incision if there has been no previous abdominal surgery. Laparoscopic assistance with mobilization of the intestine may allow augmentation through a smaller, lower incision (Hedican et al., 1999). Associated bladder procedures should be performed before opening the peritoneal cavity to minimize third space fluid loss. For gastrocystoplasty, the incision extends from the pubis to the xiphoid to allow more cephalad exposure. Augmentation cystoplasty may be performed completely by laparoscopy with or without use of a robotic system (Lorenzo et al., 2007; Passerotti et al., 2008; Wang et al., 2007). For such cases, a 12-mm camera port is placed periumbilically or supraumbilically, and up to four 5- to 8-mm working ports are used; one working port should be larger if an endostapler is to be used. Assistant ports are optional, and the use of the fourth robotic arm may aid with retraction or passage of sutures (Gundeti et al., 2008).

Management of the Native Bladder

In the past, it was recommended that the majority of the “diseased” bladder be excised in preparation for augmentation. This meant removal of the supratrigonal bladder, leaving only a small cuff for anastomosis to the intestinal segment. Despite the cuff, a relatively small area was left for anastomosis to the bowel segment; most of the bowel was approximated to itself. **Most surgeons now preserve the native bladder as long as it is widely opened to prevent a narrow-mouthed anastomosis, which can result in the augmentation segment behaving as a diverticulum** (Fig. 37.5). A sagittal incision to bivalve the bladder is generally useful (Fig. 37.6). The incision is carried from a point several centimeters cephalad to the bladder neck anteriorly to a position just above the trigone posteriorly. Such an incision allows a technically easier anastomosis to the bowel segment and leaves the native bladder to add to the overall capacity. A greater circumference for the anastomosis can be provided if need be by opening the bladder in a stellate fashion with a second transverse incision into the two bladder halves. There have been reports of penile or perineal pain in sensate boys after augmentation with preservation of the native bladder (Phelps and Malone, 2004). Although four such patients required secondary removal of bladder, similar problems have not been frequent enough to warrant routine excision at the time of augmentation.

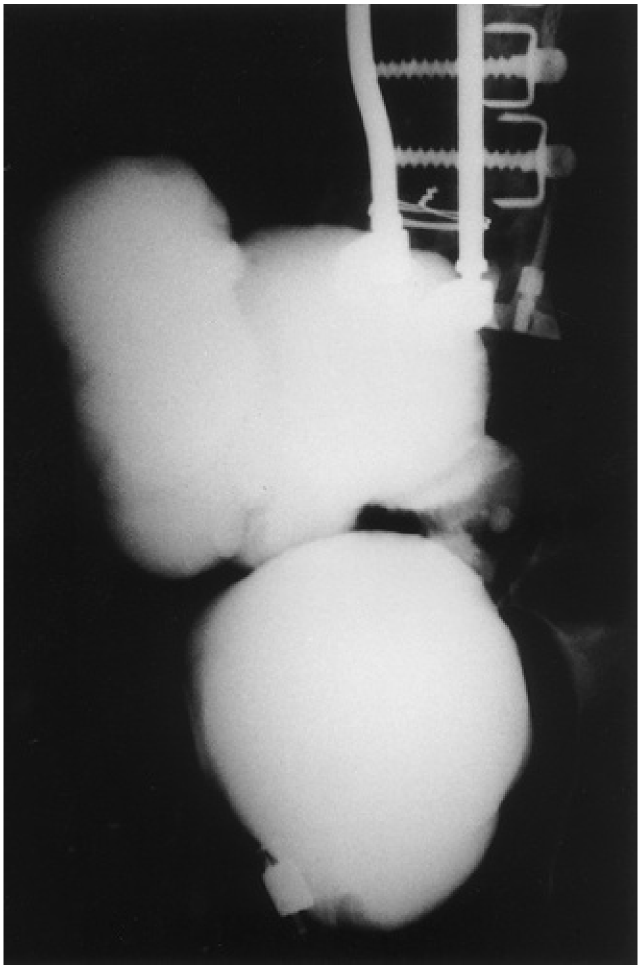

FIG. 37.5 Cystogram after augmentation demonstrates a narrow anastomosis of the bowel segment to bladder. The segment behaves like a diverticulum.

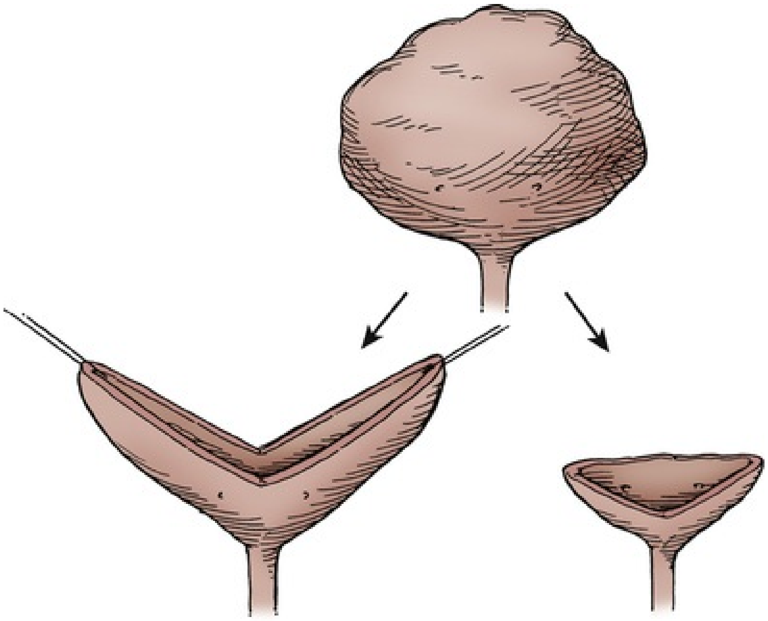

FIG. 37.6 The native bladder can be managed by supratrigonal excision of the diseased bladder. More typically, the bladder is opened widely in a sagittal plane *(left)*.

Management of Intestinal Segments

Hinman (1988) and Koff (1988) demonstrated the advantages of opening a bowel segment on its antimesenteric border with subsequent detubularization and reconfiguration of that intestinal segment. **Reconfiguration into a spheric shape provides multiple advantages, including maximization of the volume achieved for any given surface area, blunting of bowel contractions, and improvement of overall capacity and compliance.** All intact, tubular intestinal segments have been noted to generate pressures of 60 to 100 cm H_2O with contractions (Camey et al., 1991; Fowler, 1988; Kock, 1969; Light and Engelmann, 1985). Detubularization lowered the maximal contractile pressure from 63 to 42 cm H_2O in the right colon and 81 to 28 cm H_2O in ileum (Goldwasser et al., 1987). Furthermore, a shorter intestinal segment can be used to achieve the same capacity as that when left in tubular form. **Detubularization and reconfiguration should always be performed during augmentation cystoplasty.**

Mathematical models based on the length and width of the bowel segment used may predict the volume needed but are cumbersome (Rink and Mitchell, 1990). Depending on the volume needed, 20 to 40 cm of ileum or approximately

20 cm of colon are typically used for cystoplasty. This somewhat depends on the volume of the native bladder being augmented. If the cystoplasty is being done on a bladder of moderate volume that generates high pressure by uninhibited contractions, less bowel is necessary than for one that is tiny in capacity. Unless otherwise contraindicated, the surgeon should err by making the bladder too large rather than too small. Appreciation of the patient's urinary volumes also should influence the size of the bladder required. Patients with upper tract damage may make huge volumes of urine and require a larger capacity.

Ileocystoplasty

Goodwin et al. (1959) were among the first to demonstrate the numerous ways to anastomose a patch of ileum to the native bladder after the ileum was detubularized and reconfigured to achieve the most spheric shape possible.

Technique

A segment of ileum at least 15 to 20 cm proximal to the ileocecal valve should be selected. The distal portion of terminal ileum is unique from a physiologic standpoint and should be avoided. The isolated segment should be 20 to 40 cm in length, depending on patient size, native bladder capacity, and the desired final capacity. With short ureters, an extra tail of isoperistaltic ileum can be useful to reach the foreshortened ureters. This would require creation of an ileal nipple valve to prevent reflux as in the Kock or hemi-Kock pouch; this type of construction may require up to 60 cm of small intestine. **The segment to be used should have an adequate mesentery to reach the native bladder without tension.** After selection of the appropriate segment, the mesentery is cleared from the bowel at either end for a short distance to create a window. The bowel is divided at those ends, and a hand-sewn ileoileostomy or stapled anastomosis is performed. The mesenteric window at the bowel anastomosis is closed to prevent an internal hernia. The harvested ileal segment is irrigated clear with 0.25% neomycin solution and opened on its antimesenteric border (Fig. 37.7A). **The ileum is folded in a** U **shape most commonly, although longer segments can be folded further into an** S **or** W **configuration.** The ileum is anastomosed to itself with running absorbable sutures (Fig. 37.7B). The suture line should approximate the full thickness of ileum to ileum while inverting the mucosa. The anastomosis of the ileum to native bladder is easily done when started posteriorly. The anastomosis may be done in a one- or two-layer fashion, always using absorbable suture and inverting the mucosa to the lumen (Fig. 37.7C). Permanent sutures should never be used for any cystoplasty because they serve as a nidus for stone formation. A suprapubic tube is brought through the native bladder when possible and secured. The anterior aspect of the anastomosis is then completed. A drain is placed near the bladder and brought out of the pelvis through a separate stab incision. It should be removed promptly if not draining urine, particularly in neurogenic patients with a ventriculoperitoneal shunt.

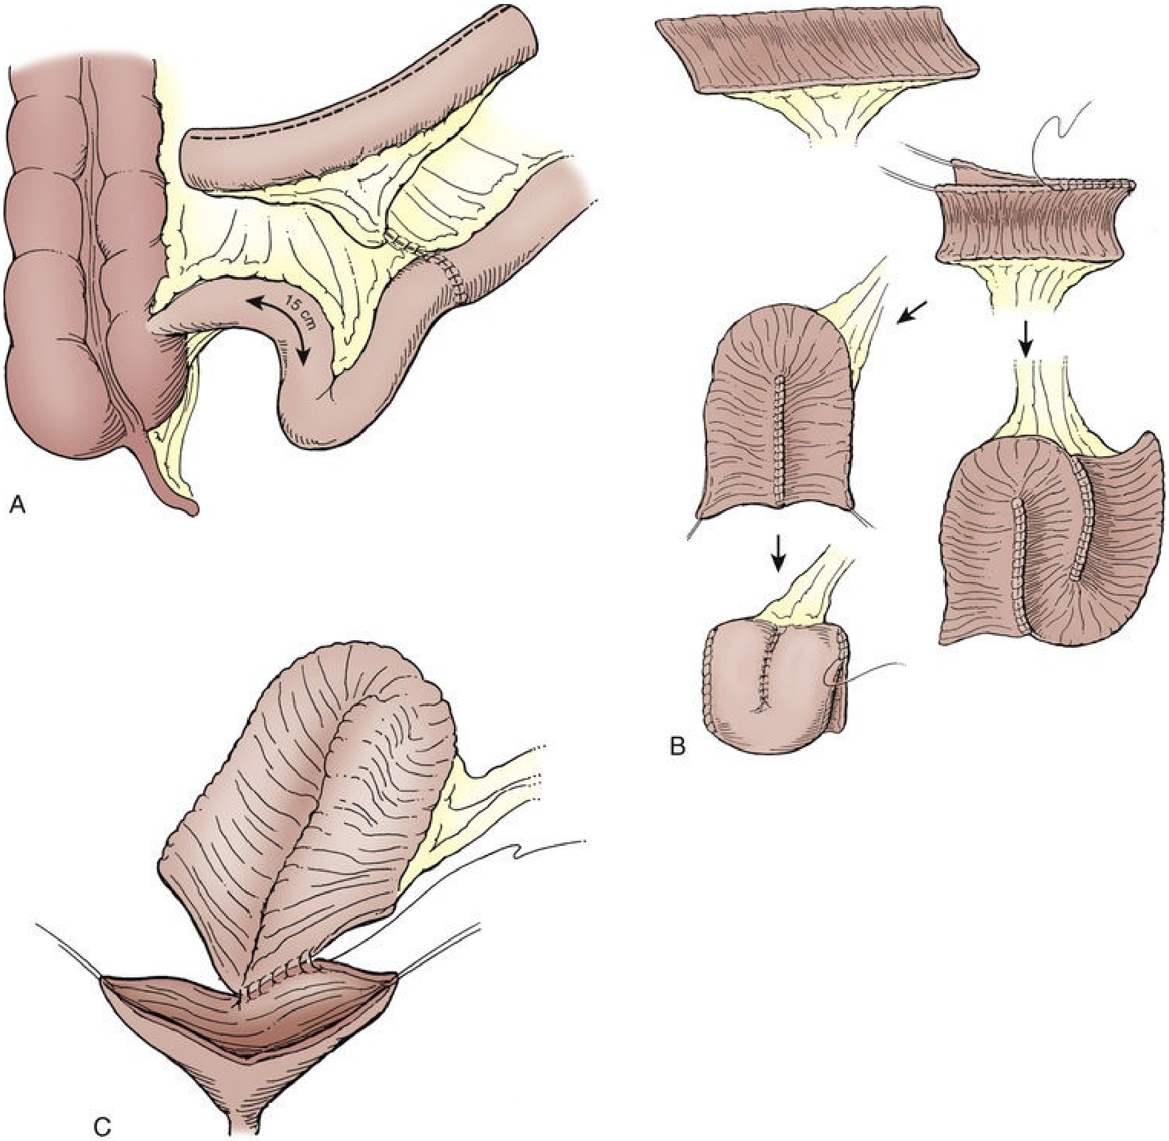

FIG. 37.7 (A) Ileocystoplasty. A 20- to 40-cm segment of ileum at least 15 cm from the ileocecal valve is removed and opened on its antimesenteric border. Ileoileostomy reconstitutes the bowel. (B) The opened ileal

segment should be reconfigured. This can be done in a U, S, or W configuration. It can be further folded as a cup patch. (C) The reconfigured ileal segment is anastomosed widely to the native bladder.

Cecocystoplasty and Ileocecocystoplasty

Couvelaire (1950) described the use of the cecum for augmentation cystoplasty, and numerous reports followed. Presently, cecocystoplasty is an uncommon operative procedure and will not be discussed because it has largely been replaced by various forms of ileocecocystoplasty. With this technique, the cecum is opened, reconfigured, and used to augment the bladder alone, leaving a segment of ileum to reach the ureters or create a continent abdominal wall stoma. Conversely, the ileal segment can be opened and used as a patch on the cecal segment before augmentation cystoplasty.

Technique

Many modifications of the technique exist, but all start with mobilization of the cecum and right colon by incising the peritoneum along the white line of Toldt up to the hepatic flexure. Between 15 and 30 cm of the terminal ileum are used. The length of the ileal segment depends on the technique used. As with all intestinal cystoplasties, before division of the bowel segment, it will reach the bladder without tension (Fig. 37.8A).

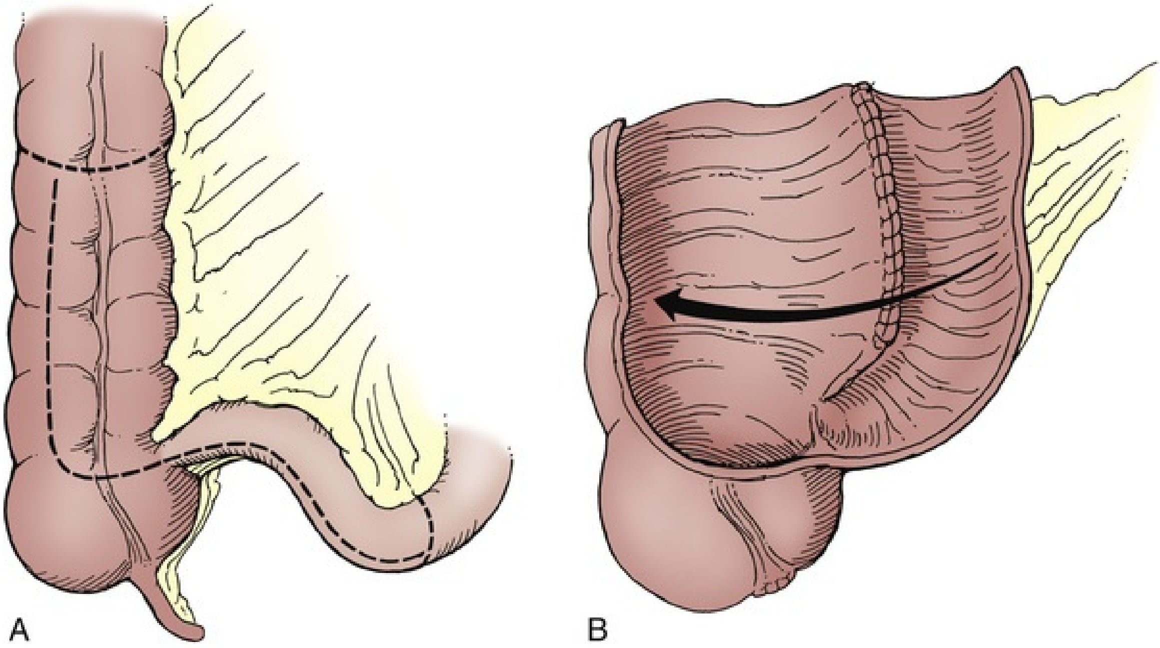

FIG. 37.8 Ileocecocystoplasty. (A) An ileocecal segment is selected. The length of segment chosen depends on the technique used. After removal, it is opened on the antimesenteric border *(dashed lines).* (B) The opened ileal and cecal segments are anastomosed to form a cup in the standard ileocecal cystoplasty.

The isolated ileocecal segment is irrigated clear with neomycin solution and opened on its antimesenteric border through the ileocecal valve for its entire length. In the typical ileocecal augmentation, the ileal and cecal segments are of equivalent length so that the borders of the open segment can be anastomosed and then folded on themselves to form a cup cystoplasty (Fig. 37.8B). The anastomosis of the reconfigured segments is done in either a one- or two-layer closure with absorbable suture. The opening should be left large enough to provide a wide anastomosis to the bivalved bladder. **If more volume is necessary, the ileal segment can be significantly longer, allowing it to be folded before anastomosis to the cecum.** The Mainz ileocecocystoplasty uses an ileal segment twice the length of the cecal segment. The compound ileocecal patch is then anastomosed to the bladder (Fig. 37.9). The mesenteric window is closed, and a suprapubic tube is placed through the native bladder and secured through the abdominal wall.

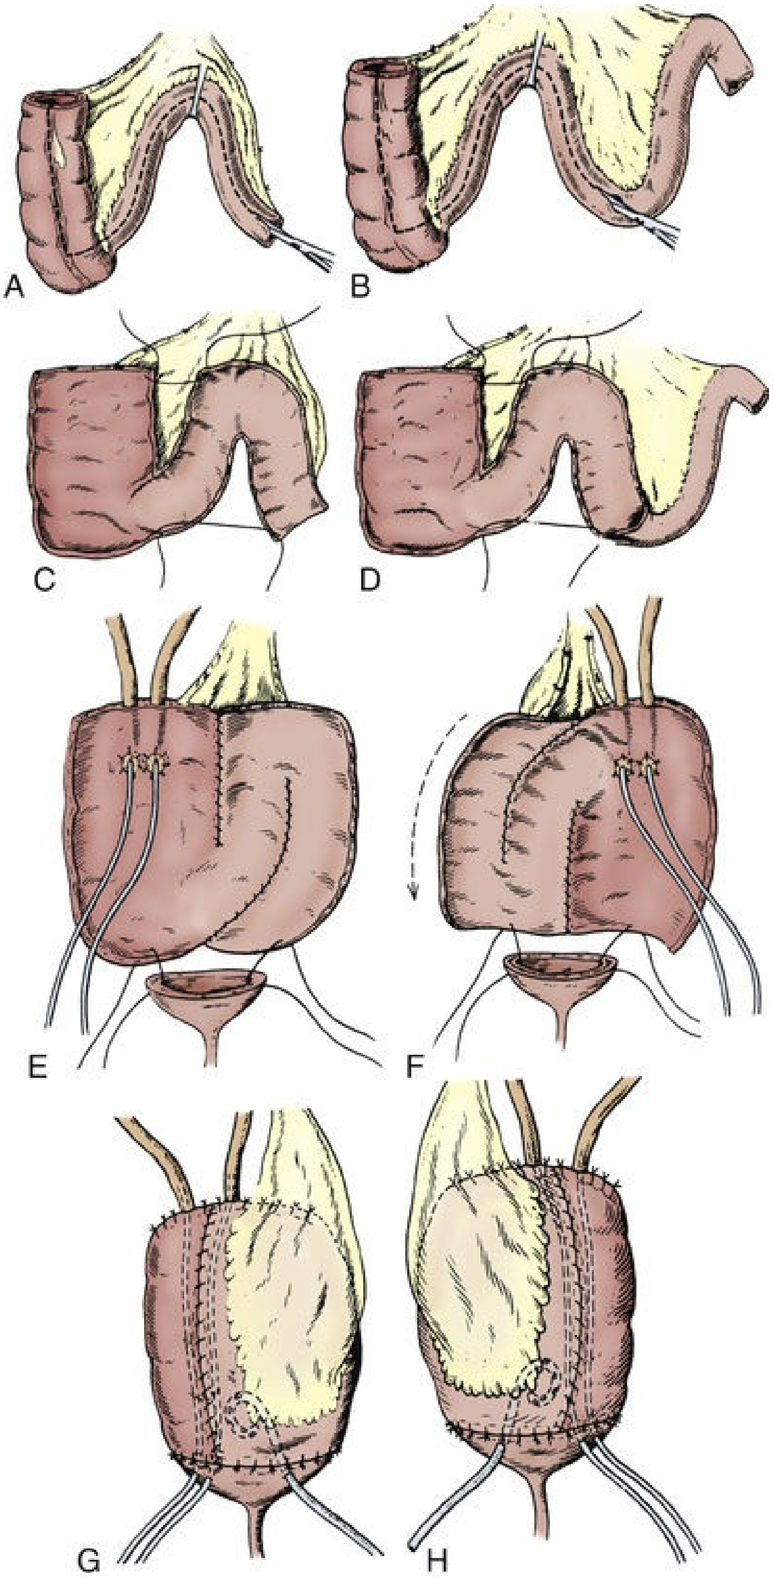

FIG. 37.9 The Mainz ileocecocystoplasty. (A and B) The ileal segment is twice the length of the cecal segment. (C and D) It is opened on the antimesenteric border. (E and F) The ureters can be reimplanted into the opened cecal segment if necessary. (G and H) The ileocecal segment is

anastomosed to the native bladder. (From Thuroff JW, Alken P, Hohenfellner R: The Mainz pouch (mixed augmentation with ileum and cecum) for bladder augmentation and continent diversion. In King LR, Stone AR, Webster GD, editors: *Bladder reconstruction and continent urinary diversion,* Chicago, 1987, Year Book, p 252.)

Appendix

One potential advantage of ileocecocystoplasty is the presence of the appendix. Particularly in children, the appendix is useful in creation of a reliable continent abdominal wall stoma. The appendix may be removed with a small cuff of cecal wall and tunneled into the native bladder or a tenia of the cecal segment to provide a continence mechanism. Likewise, it may be left in situ and the base safely tunneled beneath a tenia. If the appendix is not to be used, an appendectomy is performed with standard ileocecocystoplasty.

Ileocecal Valve

The ileocecal segment has been used extensively in the adult population undergoing reconstruction and bladder replacement. It has been used less frequently in children because the majority of patients undergoing augmentation cystoplasty do so for neurogenic dysfunction affecting bladder and bowel. Removal of the ileocecal valve in such children can result in intractable diarrhea (Gonzalez and Cabral, 1987; King, 1987). Use of the ileocecal valve in such patients should be avoided unless other advantages of the segment outweigh the risk of diarrhea and fecal incontinence.

There are potential advantages to the use of the ileocecal segment. Antireflux tunnels can easily be performed into the tenia of the cecum when necessary. Again for the short ureter, a tail of ileum can be left intact to bridge the gap and the imbricated ileocecal valve used for antireflux. The same imbrication technique can be used to create a continent abdominal wall stoma similar to that used in the Indiana Pouch (Cain and Husmann, 1994; Cain et al., 1999).

Sigmoid Cystoplasty

Use of the sigmoid colon for augmentation cystoplasty was first reported by Lemoine in 1912 (Charghi et al., 1967), and it continues to be used commonly. **Because of the strong unit contractions of the sigmoid, it is imperative to detubularize and reconfigure the segment to provide maximal compliance**

and disruption of contractions.

Technique

Between 15 and 20 cm of sigmoid colon are identified and mobilized. The mesentery is transilluminated to identify the vascular arcade to the segment. After identification of this blood supply, the surgeon must ensure that the segment can reach the bladder without tension. The bowel segment is divided between clamps, and a colocolostomy performed (Fig. 37.10A). The remainder of the abdominal cavity should be carefully packed to prevent contamination from the open sigmoid segment. Detubularization and reconfiguration are done in a fashion determined by the surgeon's preference. The sigmoid patch is anastomosed to the bivalved bladder in a manner similar to that previously described for ileocystoplasty. Again, a large suprapubic tube is brought out through the native bladder and secured to the bladder and skin exit sites.

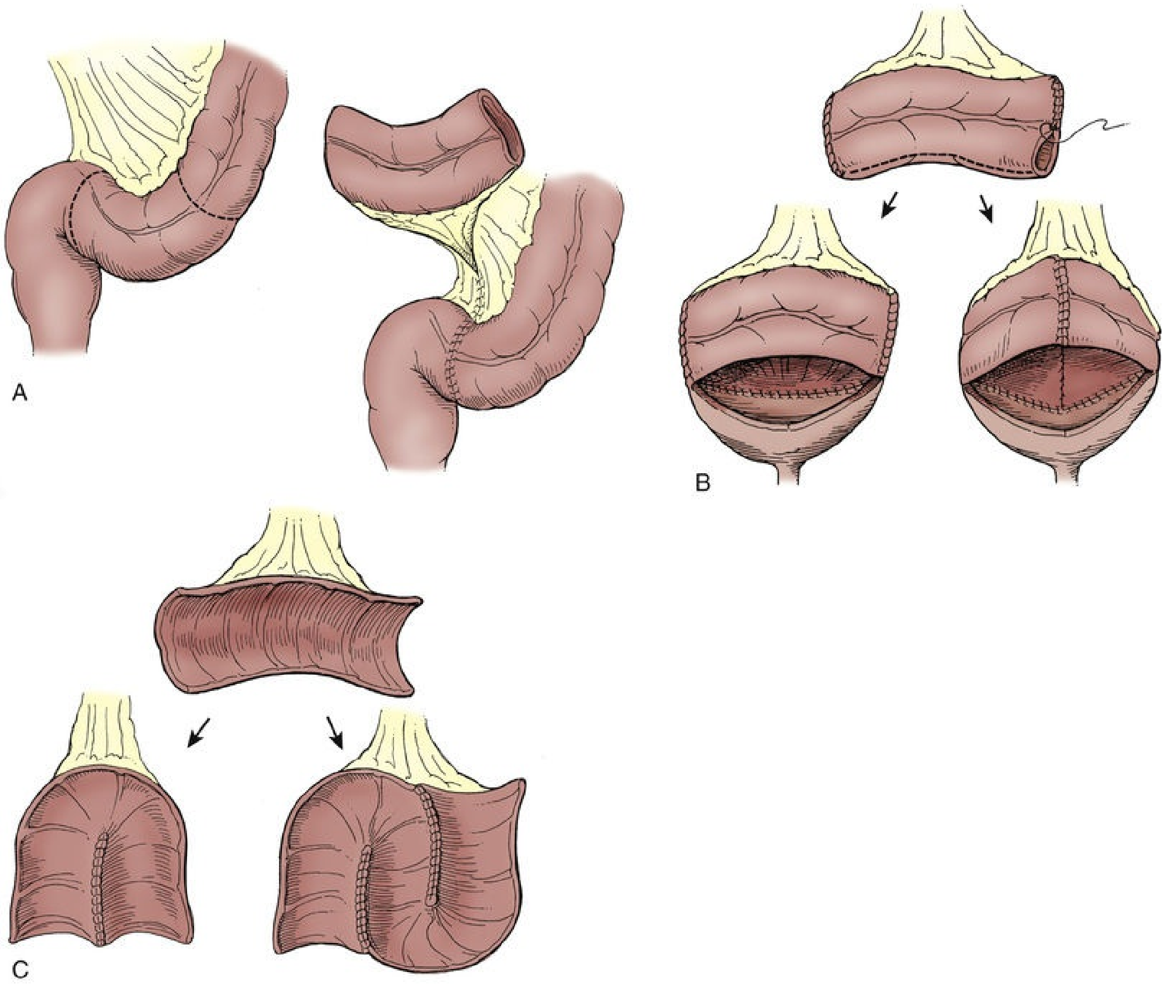

FIG. 37.10 Sigmoid cystoplasty. (A) A sigmoid segment of adequate length is removed from the gastrointestinal tract, and a colocolostomy is performed. (B) In the Mitchell technique the two opened ends are closed. The antimesenteric border is incised, and the segment is anastomosed to the bivalved bladder. It may be rotated 180 degrees to allow an easy fit. (C) The opened sigmoid segment can be reconfigured into a U or S configuration, which may lower pressure.

Reconfiguration of Sigmoid.

In general, sigmoid colon segments are reconfigured in one of two ways. Mitchell (1986) suggested closing the two ends and then opening the segment longitudinally opposite its blood supply. The segment easily fits on the bivalved bladder in either the sagittal or coronal plane (Fig. 37.10B). More radical reconfiguration, and perhaps breakup of unit contractions, may be achieved by folding the sigmoid segment in a U shape similar to that described for ileocystoplasty (Sidi et al., 1987a) (Fig. 37.10C). A slightly longer segment of sigmoid may be necessary for effective reconfiguration in this manner.

Gastrocystoplasty

Two techniques have been described for gastrocystoplasty. Leong and Ong (1972) described the use of the entire antrum with a small rim of body for gastric replacement. Continuity of the upper gastrointestinal tract was restored by Billroth I gastroduodenostomy. A wedge-shaped segment of body based on the midportion of the greater curvature may also be used (Adams et al., 1988) but contains a higher concentration of acid-producing cells. For several reasons, the use of gastrocystoplasty in children has been abandoned except in rare cases, and it consequently is not discussed in any detail. Interested readers may refer to prior editions of this chapter.

Postoperative Management

Early Management

Care of patients after cystoplasty is similar regardless of the segment used in the procedure. **Typically, all patients have been maintained on nasogastric decompression until bowel function recovers, although two studies** (Erickson et al., 2007; Gundeti et al., 2006) **have suggested that nasogastric suction may not be necessary after ileocystoplasty. Attention to fluid and electrolyte management is important because third space losses may be significant after extensive reconstructive surgery.** Although increasingly common in the adult literature, an enhanced recovery after surgery (ERAS) protocol was recently analyzed for pediatric patients undergoing reconstructive procedures. Specifically, this protocol was employed prospectively in patients who had a bowel anastomosis with the intent on earlier recovery of bowel function, reduced length of stay, and decreased overall complication rate. The protocol included no bowel preparation, administration of preoperative oral carbohydrate liquid, avoidance of opioids, regional anesthesia, laparoscopy in select cases, lack of postoperative nasogastric decompression, early feeding, and early stoppage of intravenous fluids (Rove et al., 2018). Despite some inherent biases noted by the authors, this single-center prospective study showed excellent adherence to the protocol by hospital staff and concluded that maintenance of euvolemia and early feeding contributed to early return of bowel function. Opioid usage was less, patients left the hospital almost 2½ days sooner, complication grade per patient decreased, and there was no difference in 90-day complication rates or early postoperative emergency department admission if ERAS was employed. Although these findings were not statistically significant, they suggest the need for a multi-institutional study with larger numbers to confirm these important trends.

Continuous drainage of the bladder is achieved by suprapubic cystostomy. Mucus production from small or large bowel may be excessive and can potentially occlude the drainage catheter. **The suprapubic tube should be irrigated at least three times daily and whenever drainage is slowed by mucus.** Extravesical drains may be removed after several days, if drainage of urine is not apparent. The drains are usually removed more promptly in patients with a ventriculoperitoneal shunt to minimize risk of infection. Some surgeons prefer to perform a cystogram before patient discharge; others wait approximately 3 weeks for the study before clamping the suprapubic tube. All patients should begin CIC every 2 to 3 hours during the day and one or two times at night initially. The suprapubic tube is removed after regular catheterization is successfully underway. The duration between catheterizations is gradually increased over several weeks but should not exceed 4 to 5 hours during the day. Patients without neurologic impairment may eventually attempt to void spontaneously. All should check postvoid residual volumes and continue catheterizations if the residuals are significant.

Late Management

Routine radiographic surveillance of the upper urinary tract is indicated at 6 weeks, 6 months, and 1 year after augmentation cystoplasty. Most of such surveillance may be done with ultrasonography. Serum electrolytes, BUN, and creatinine levels along with urine cultures are performed several times in the first year after surgery. All positive urine cultures need not be treated in patients on CIC. Certainly symptomatic cystitis or infections involving urea-splitting organisms should be cleared. Evaluation by ultrasonography and serum chemistries is then appropriate once a year. Eventually, yearly endoscopy for tumor surveillance may be performed. No consensus exists about the timing or frequency of cystoscopic examination. Higuchi et al. (2010) have suggested that surveillance may be of greater yield in patient populations at greater risk, such as valve patients who are on immunosuppression after transplantation or exstrophy patients with their inherent increased risk for bladder adenocarcinoma. After the report of Castellan et al. (2012), surveillance may be of higher yield after gastrocystoplasty. No experience demonstrates that routine surveillance is cost effective or successful in this population (Higuchi et al., 2011; Kokorowski et al., 2011), and the Mayo Clinic group has suggested that such surveillance be discontinued (Higuchi et al., 2011).

Results and Complications of Augmentation Cystoplasty

The effect of cystoplasty on the patient should be considered in two ways. One must first consider the effect of removing a relatively small portion of the gastrointestinal tract for use in urinary reconstruction. **Any more than rare development of gastrointestinal problems would be prohibitive, even if results were perfect from the standpoint of the urinary bladder.** Second, the effect of augmentation cystoplasty on the urinary bladder must be reviewed. The primary goal of augmentation is to provide a compliant urinary reservoir. **Therefore the main considerations after augmentation are the storage pressure and capacity that are achieved. Any other effects on the urinary bladder are side effects or complications that exist because bowel is not a perfect physiologic substitute for native bladder. Approximately one-third of patients require further surgery after augmentation cystoplasty because of various problems** (Kispal et al., 2011; Metcalfe et al., 2006).

Gastrointestinal Effects

Postoperative bowel obstruction is uncommon after augmentation cystoplasty, occurring in approximately 3% of patients after augmentation (Gearhart et al., 1986; Hollensbe et al., 1992; King, 1987; Mitchell and Piser, 1987; Rink et al., 1995a). **The rate of obstruction is equivalent to that noted after conduit diversion or continent urinary diversion** (McDougal, 1992b). Delicate handling of tissues, closure of mesenteric windows, and elimination of sites of internal herniation help to avoid obstruction. Occasional series have suggested differing rates of bowel obstruction depending on the segment used. These differences have not been consistent in most series and are therefore likely not significant.

Reports of chronic diarrhea after bladder augmentation alone have been rare. Diarrhea can occur after removal of large segments of ileum from the gastrointestinal tract, although the length of the segments typically used for augmentation rarely is problematic unless other problems coexist. The use of a typical colonic segment for augmentation only rarely results in a change in bowel function. **Removal of a segment from the gastrointestinal tract including the ileocecal valve is more likely to cause diarrhea.** Some children with neurogenic impairment depend on constipation for fecal continence. Removal of the ileocecal valve from the gastrointestinal tract may significantly decrease bowel transit time. Loss of the valve can also allow bacterial backflow into the ileum, and the organisms may interfere with fat and vitamin B_{12} metabolism. Studies have noted chronic diarrhea in 10% to 23% of patients with neurogenic dysfunction after displacement of the ileocecal valve (King, 1987; Roth et al., 1995), although the risk may be lower for carefully selected patients (Husmann and Cain, 1999).

Ileum is the sole site of vitamin B_{12} absorption. **Removal of the distal ileum from the gastrointestinal tract may therefore result in vitamin B_{12} deficiency and megaloblastic anemia. The terminal 15 to 20 cm of ileum should not be used for augmentation, although problems may arise even if that segment is preserved** (Racioppi et al., 1999; Steiner and Morton, 1991). Again, the risk is greater if longer segments of ileum are used as with continent diversion. Of patients followed over 5 years after a Kock pouch procedure, 35% were found to be deficient in vitamin B_{12} in one series (Akerlund et al., 1989). In general, the length of ileum used for augmentation is less than one-half that used for a Kock pouch, so vitamin B_{12} deficiency seems unlikely after routine bladder augmentation. Canning et al. evaluated 26 patients after bladder augmentation or replacement and found no patients with either fat malabsorption or vitamin B_{12} deficiency (Canning et al., 1989). However, only three patients were followed for longer than 3 years, and longer observation is necessary because existing body vitamin B_{12} storage may last considerably longer (Stein et al., 1997a). VanderBrink et al. (2010) found low or low-normal B_{12} levels in 41% of patients evaluated a mean of 83 months after ileocystoplasty and were able to increase those levels by giving the oral vitamin.

Early satiety may occur after gastrocystoplasty but usually resolves with time. Disorders of gastric emptying should be extremely rare, particularly when gastric body is used.

Bladder Compliance After Augmentation

An early lesson of past clinical experience with augmentation cystoplasty has been the value of detubularization and reconfiguration of the bowel segment (Hinman, 1988; Koff, 1988). Some surgeons with extensive experience in augmentation cystoplasty have concluded that ileum is superior to other segments in terms of compliance after augmentation, although controlled experimental examination of similarly sized bowel segments is lacking (Goldwasser and Webster, 1986; Rink and McLaughlin, 1994; Studer and Zingg, 1997). On the contrary, one report has suggested superior results with colon compared with ileum (Shekarriz et al., 2000) when a longer colonic segment reconfigured in a U shape was used. Good results have been achieved with all segments in most cases, and it is more important to use a bowel segment well than to choose a particular bowel segment for every patient.

Occasional problems with pressure after augmentation cystoplasty occur from uninhibited contractions, apparently in the bowel segment. It is extremely rare not to achieve an adequate capacity or flat tonus limb unless a technical error has occurred with use of the bowel segment. When pressure contractions occur in the bladder after augmentation, they are often noted in a rhythmic or sinusoidal pattern, occasionally with increasing amplitude (Fig. 37.11). Contractions that begin at low amplitude later in filling and progress only near capacity may be of no clinical significance. Early contractions of higher pressure may result in persistent incontinence, delayed perforation, hydronephrosis, or vesicoureteral reflux. If patients have such clinical problems after augmentation, repeat urodynamic testing is indicated because one cannot assume the bladder is compliant after augmentation. **Rhythmic contractions have been noted postoperatively with all bowel segments, although ileum seems the least likely to demonstrate remarkable urodynamic abnormalities, and the stomach the most likely.**

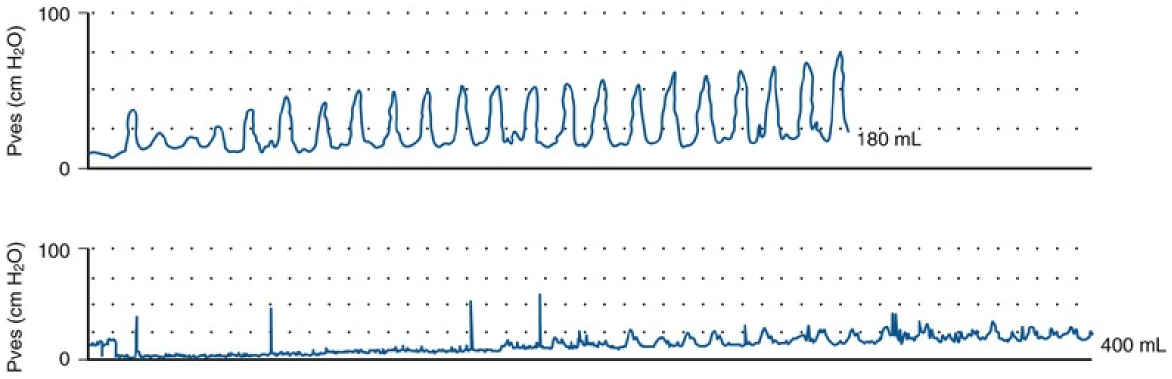

FIG. 37.11 Rhythmic, sinusoidal contractions *(top)* may occur after bladder augmentation, in this case with stomach. Contractions of significant amplitude early in filling occasionally require secondary augmentation. After secondary augmentation with ileum *(bottom)*, urodynamics show that contractions still occur but are much lower in pressure and occur later in filling.

After bladder augmentation or replacement, some urodynamic evaluation has suggested that colonic segments, whether cecum or sigmoid, still generate more pressure than ileum despite detubularization (Berglund et al., 1987; Jakobsen et al., 1987; Lytton and Green, 1989; Studer and Zingg, 1997; Thuroff et al., 1987), although other work has suggested that pressure contractions from the colon decrease with time (Hedlund et al., 1984; Sidi et al., 1986b). Goldwasser's review of enterocystoplasty demonstrated contractions greater than 15 cm H_2O in 42% of patients after ileocystoplasty versus in 60% of those after colocystoplasty (Goldwasser et al., 1987). Significant contractions, defined as those above 40 cm H_2O at a volume below 200 mL, were not noted in any of the ileal augmentations but persisted in 10% of cystoplasties. Their work agreed with that of Berglund et al. (1987) and Studer and Zingg (1997) in suggesting that ileal reservoirs have lower basal pressures and less motor activity. None of these studies critically controlled for the size of the bowel segment or the technique in which they were used. In fact, a canine model of partial bladder replacement using identically sized segments failed to demonstrate in vitro or in vivo differences between the gastrointestinal segments (Nelson et al., 2005).

Rhythmic contractions after gastrocystoplasty have been noted in up to 62% of patients (Adams et al., 1988; Atala et al., 1993; Gosalbez et al., 1993a; Roth et al., 2000), although the use of antrum or a larger gastric segment may have lessened the risk for such contractions (Adams et al., 1995; DeFoor et al., 2003a; Koraitim et al., 1999; Kurzrock et al., 1998; Leong, 1988).

In perhaps the most extensive experience with pediatric bladder augmentation, Hollensbe et al. at Indiana University found that approximately 5% of patients had significant uninhibited contractions after augmentation cystoplasty causing clinical problems (1992). Pope and Rink (1999) found that 6% of more than 300 patients required secondary augmentation of a previously augmented bladder for similar problems. With longer follow-up, the same group has eventually performed reaugmentation in 9% of patients (Metcalfe et al., 2006). These secondary augmentations represent true failures of the cystoplasty to achieve their primary objectives, capacity, and compliance. In that series, sigmoid colon followed by stomach and then ileum were more likely to require reaugmentation. A colonic segment closed at the ends and not reconfigured otherwise was typically used in that experience. Other studies have suggested that stomach is more likely than colon to require secondary intervention (Castellan et al., 2012; El-Ghoneimi et al., 1998).

Metabolic Complications

Chloride Absorption and Acidosis.

The first recognized metabolic complication related to storage of urine within intestinal segments was the development of hyperchloremic metabolic acidosis after ureterosigmoidostomy (Ferris and Odel, 1950). Patients with this metabolic derangement were noted to have fatigue, weakness, anorexia, and polydipsia. **Koch and McDougal** (1985) **demonstrated the mechanisms by which acid is absorbed from urine in contact with intestinal mucosa.** Resorption in the form of ammonium results in chronic acid loading. Patients with normal renal function are usually able to handle the resorbed load of chloride and acid without frank acidosis. **Mitchell and Piser (1987) noted that almost every patient after augmentation with an intestinal segment had an increase in serum chloride and a decrease in serum bicarbonate level, although full acidosis was rare if renal function was normal.** Acidosis and electrolyte disturbances requiring treatment have been reported despite normal renal function (Schmidt et al., 1973; Whitmore and Gittes, 1983). Such derangements may be debilitating to the patient if not recognized and treated (Heidler et al., 1979). **Hall et al.** (1991) **noted that there is an increase in the urinary acid load with wasting of bony buffers even in the absence of frank acidosis**. Such wasting may result in bone demineralization and could cause retarded growth in children after augmentation cystoplasty (Abes et al., 2003; Hafez et al., 2003; Vajda et al., 2003). Patients with acidosis should receive bicarbonate therapy. Nurse and Mundy (1989) have suggested that arterial blood gas values may be more sensitive than serum bicarbonate or chloride levels for detecting acidosis. Stein et al. (1998) felt that measurements of arterial blood gas for base deficit allowed early treatment of acidosis and avoidance of bone demineralization. In severe cases of acidosis, chloride transport can be blocked with chlorpromazine and nicotinic acid.

Although jejunum is rarely used for bladder reconstruction, storage of urine in this segment results in a unique metabolic pattern of hyponatremic,

hypochloremic, and hyperkalemic metabolic acidosis. The problem is often associated with significant hypovolemia.

Hyperchloremic, metabolic acidosis was avoided by gastrocystoplasty (Adams et al., 1988; Ganesan et al., 1991; Kurzrock et al., 1998) even in patients with impaired renal function; however, acid secretion was found to result in several unique complications after gastrocystoplasty. Episodes of hypokalemic and hypochloremic alkalosis were noted in some patients, particularly during an acute gastrointestinal illness with dehydration (Ganesan et al., 1991; Gosalbez et al., 1993b; Hollensbe et al., 1992). Acidic urine could irritate the native bladder and any exposed skin and was particularly bothersome in patients with intact sensation. Mitchell's group described this hematuria-dysuria syndrome well (Nguyen et al., 1993; Plaire et al., 1999). Ironically, stomach in the urinary tract may have performed best in the most complex of patients when combined with ileum to result in a more metabolically neutral reservoir (Austin et al., 1997, 1999, 2001).

Patient Growth.

Delayed or slowed growth in some children after intestinal cystoplasty has previously been recognized (Mundy and Nurse, 1992; Wagstaff et al., 1991; Wagstaff et al., 1992). A delay in linear growth was noted in 20% of almost 200 pediatric patients without any gross biochemical abnormalities. However, no control patients were included in that series. Body habitus and growth are difficult to predict in children with myelodysplasia, who make up the majority in most series of augmentation cystoplasty. Gros et al. (2000) evaluated growth in exstrophy patients. Patients requiring augmentation were matched retrospectively with a similar group not requiring bladder augmentation. Only 1 patient was noted to have acidosis in either group. Other factors that may affect growth, such as UTI, were not controlled. Of 17 patients with adequate measurements before and after cystoplasty, 14 (82%) had a decline in percentile height postoperatively. The decline corresponded to a ½-inch decrease in expected height. The pattern of growth was significantly different between patients with and without augmentation in the series. That series is small, and no evaluation of familial growth patterns or ultimate height was possible; however, the findings are worrisome, particularly because Feng et al. (2002) noted similar differences in exstrophy patients. In the absence of any serum abnormalities, the exact mechanism of delayed growth was not evident, although it seems likely to be related to subclinical acidosis (Bushinsky, 1989; Koch and McDougal, 1988;

Hochstetler et al., 1997). Taskinen et al. (2008) found no adverse effect on longitudinal growth after bladder augmentation in the exstrophy population.

Three recent series did show effect of bowel cystoplasty on bone mineral density in some patients (Abes et al., 2003; Hafez et al., 2003; Vajda et al., 2003), whereas two others did not (Haas et al., 2012; Mingin et al., 2002). One must be careful to determine whether any such changes are the result of augmentation cystoplasty or the underlying pathology (Boylu et al., 2006; Haas et al., 2012; Taskinen et al., 2007). Better analysis of subtle metabolic alterations after enterocystoplasty may establish better understanding of the effect on growth, minimize changes, or aid in early treatment to avoid the complication (Brkovic et al., 2004).

Alkalosis.

The secretory nature of gastric mucosa may at times be detrimental to the patient and can result in two unique complications of gastrocystoplasty. Episodes of hypokalemic, hypochloremic metabolic alkalosis after acute gastrointestinal illnesses were noted in 5 of 37 patients after gastrocystoplasty (Hollensbe et al., 1992). The episodes were significant enough to require hospitalization in all patients and were recurrent in 2 patients. Of the 5 patients who developed the complication 3 had renal insufficiency and would not have been good candidates for augmentation with other segments because of acidosis. Ganesan et al. (1991) noted similar episodes of alkalosis in 5 of 21 patients with renal insufficiency after gastrocystoplasty. **Patients with the primary indication for consideration of gastrocystoplasty may be the ones at greatest risk for this unusual complication.** It has been proposed that the alkalosis results from ongoing chloride loss from the gastric segment in the bladder in the face of decreased oral intake. Gosalbez et al. (1993b) demonstrated persistently increased fractional excretion of chloride despite profound hypochloremia, suggesting that inappropriate gastric secretion is likely the primary mediator. One patient in their series eventually required resection of three quarters of the gastric segment in the bladder because of recurrent problems with alkalosis, and several required therapy with H_2 blockers or H^+/K^+ ion pump inhibitors. All patients and families should be made aware of this potential problem because it has been reported to occur intermittently in 3% to 24% of patients. A composite reservoir of stomach and ileum or colon may provide a more metabolically neutral reservoir (Austin et al., 1997, 1999, 2001; McLaughlin et al., 1995), although these have typically been constructed in only very complex patients or circumstances.

Hematuria-Dysuria Syndrome.

Acid secretion by gastric mucosa may result in another unique problem after gastrocystoplasty, the hematuria-dysuria syndrome. Mitchell's group characterized this syndrome well (Nguyen et al., 1993; Plaire et al., 1999). **Almost all patients after gastrocystoplasty with normal sensation have occasional hematuria or dysuria with voiding or catheterization beyond what is expected with other intestinal segments** (Leonard et al., 1999). All patients should be warned of this potential problem, although in most patients these symptoms are intermittent and mild and do not require treatment. The problem led one group to recommend avoiding gastrocystoplasty in patients with bladder exstrophy (El-Ghoneimi et al., 1998). The dysuria is not as problematic in patients with neurogenic dysfunction. In the experience of Nguyen et al. (1993), 36% of patients developed signs or symptoms of the hematuria-dysuria syndrome after gastrocystoplasty; 14% of patients required treatment with medications, including 9% on a regular basis. Patients who are incontinent or have decreased renal function are at increased risk. Others have noted a similar requirement for short-term and chronic medical therapy (Adams et al., 1995; Castellan et al., 2012; Hollensbe et al., 1992). The symptoms of the hematuria-dysuria syndrome do respond well to H_2 blockers and hydrogen ion pump blockers. Bladder irrigation with baking soda may also be effective. It has been demonstrated that urinary pH may decrease remarkably after meals in patients who have undergone gastrocystoplasty (Bogaert et al., 1995). The signs and symptoms of the hematuria-dysuria syndrome are most likely secondary to acid irritation. Work has suggested that *Helicobacter pylori* may play a role in this complication (Celayir et al., 1999). Such problems can occur but are less frequent after antral cystoplasty because there is a smaller load of parietal cells (Ngan et al., 1993).

Acid in the urine may also cause external irritation. Leong first noted glanular excoriation after gastrocystoplasty in a patient with voiding symptoms (Ngan et al., 1993). Nguyen et al. noted skin excoriation in 8 of 57 patients after gastrocystoplasty; all 8 patients had some element of urinary incontinence (Nguyen et al., 1993). **It is imperative to achieve reliable urinary continence in patients undergoing gastrocystoplasty because urinary leakage may result in the exposure of the skin to gastric secretions and in gastric secretions that are poorly diluted.** Dilution is important; Reinberg et al. (1992) reported a perforation of a gastric segment in a defunctionalized bladder after gastrocystoplasty. They evaluated the influence of urine on gastrocystoplasties in dogs (Castro-Diaz et al., 1992). The animals developed marked inflammation of the gastric segment and native bladder after creation of a dry gastrocystoplasty; 3 of 9 dogs developed ulceration and perforation. Use of H_2 blockers resulted in some protection for the animals; however, such a clinical situation should certainly be avoided. Rare perforations and ulcerations have been noted clinically without defunctionalization (El-Ghoneimi et al., 1998; Mingin et al., 1999a).

Mucus

Intestinal segments continue to produce mucus after placement in the urinary tract. The material can potentially impede bladder drainage during voiding or CIC, particularly in pediatric patients in whom the use of small-caliber catheters is necessary. Mucus may serve as a nidus for infection or stone formation when it remains in the bladder for long periods of time. Mucus production often increases after cystoplasty in the presence of cystitis. Kulb et al. (1986) showed experimentally in dogs that colonic segments produce more mucus than ileum and that gastric segments produce the least amount. This has been noted clinically as well; most patients do not require any routine bladder irrigations for mucus after gastrocystoplasty. Villous atrophy in the ileum has been documented after placement in the urinary tract. It has been suggested that such atrophy may result in decreased mucus production (Gearhart, 1987), although laboratory demonstration of any decrease in production with time has not been evident (Murray et al., 1987). Hendren and Hendren (1990) noted a decrease in mucus production from colonic segments over years; however, others have not been impressed with such changes (Rink et al., 1995a). Glandular atrophy in colonic mucosa has not been noted histologically (Mansson et al., 1984). **Routine use of daily bladder irrigations to prevent mucus buildup may minimize complications of enterocystoplasty such as UTI and calculi** (Hensle et al., 2004).

Urinary Tract Infection

Bacteriuria is common after intestinal cystoplasty, particularly in patients requiring intermittent catheterization (Gearhart et al., 1986; Hendren and Hendren, 1990; King, 1991). Recent experience with bowel neobladders has demonstrated that patients who are able to spontaneously void to completion often maintain sterile urine. **It appears that use of CIC is a prominent factor**

in the development of bacteriuria in patients who have undergone augmentation cystoplasty. Bacteriuria has been noted even when patients are maintained on daily oral antibiotics or antibiotic irrigation (Casale et al., 1999; Gearhart et al., 1986). In Hirst's (1991) experience, persistent or recurrent bacteriuria occurred in 50% of patients augmented with sigmoid colon versus 25% of those after ileocystoplasty. Hollensbe et al. (1992) noted bacteriuria much more commonly in patients requiring CIC regardless of the segment considered. The incidence of symptomatic cystitis after cystoplasty likely depends on the length of follow-up and the diligence with which symptoms are sought. All patients and families should be told to expect some signs or symptoms of cystitis. Recurrent episodes of symptomatic cystitis requiring treatment occurred in 23% of patients after ileocystoplasty, 17% of patients after sigmoid cystoplasty, 13% after cecocystoplasty, and 8% after gastrocystoplasty at Indiana University (Hollensbe et al., 1992). Febrile UTIs occurred in 13% of those 231 patients after augmentation. The same trend among different bowel segments was noted for febrile infections, although there was no statistically significant difference among the various segments. **The incidence of pyelonephritis after augmentation cystoplasty, as long as upper tract problems are corrected, is similar to that noted for conduit diversion, whether refluxing or not** (McDougal, 1992b). Infections may occasionally be more problematic in an immunocompromised patient (Alfrey et al., 1997), but that has not always proven to be the case (Traxel et al., 2011).

Not every episode of asymptomatic bacteriuria requires treatment in patients performing CIC. Bacteriuria should be treated in the presence of significant symptoms such as incontinence or suprapubic pain and may be treated if hematuria, foul-smelling urine, or remarkably increased mucus production occurs. **Bacteriuria should be treated if the urine culture demonstrates growth of a urea-splitting organism that may lead to stone formation.** To minimize infection, patients requiring CIC must perform it on a regular basis to avoid increased reservoir pressures and must work to empty the bladder completely. Special care must be taken by patients catheterizing through a continent abdominal wall stoma. Such patients may have more difficulty completely emptying the bladder from a nondependent stoma. Most can do so with effort (Ludlow et al., 1995). Although catheterization is not routinely a sterile technique, use of proper clean technique should be emphasized.

Calculi

Another long-term complication of augmentation cystoplasty is bladder calculus formation. In the early 1990s, several series reported calculi in 18% of patients after augmentation cystoplasty (Hendren and Hendren, 1990; Hirst, 1991). Blyth et al. noted calculus formation in 30% of such patients; they found that patients catheterizing through an abdominal wall stoma have the highest risk, likely because of incomplete emptying (Blyth et al., 1992). Palmer et al. (1993) noted urolithiasis in 52% of patients after augmentation cystoplasty. Metcalfe et al. (2006) noted a 15% rate of bladder stone formation in 500 patients with long-term follow-up after enterocystoplasty; the reasons for these remarkable differences are not clear. **Most bladder stones in this patient population are composed of struvite, and bacteriuria is an important risk factor.** Any infection with a urea-splitting organism should therefore be treated. All patients requiring CIC, particularly those who have already formed stones, should make every effort to empty the bladder completely with each catheterization. If stones are found in patients voiding spontaneously after augmentation, the adequacy of emptying should be re-evaluated. The association of urinary stasis with stone formation is well established. Routine bladder irrigations to avoid buildup of inspissated mucus may remove a nidus for stone formation. The group at Indiana and others have stressed irrigations and asked patients and families to routinely irrigate the bladder several times a day after augmentation (Hensle et al, 2004; Rink et al., 1995a). Stones have been noted after the use of all intestinal segments with no significant difference noted between small and large intestine. Struvite stones are less likely after gastrocystoplasty (Kaefer et al., 1998; Kronner et al., 1998a), likely because of decreased mucus production and acid that minimizes bacteriuria. Uric acid calculi have been noted in the bladder after gastrocystoplasty (Kaefer et al., 1998). Clearly, any foreign body will serve as a nidus for stone formation; the use of permanent sutures or staples in the urinary tract should be avoided during enterocystoplasty. In a case control analysis, the presence of bladder stones and use of intestinal interposition may be independent risk factors for the development of upper tract stones in children with neuropathic bladders (Stephany, 2014). Khoury et al. (1997) looked for metabolic problems in patients after augmentation and noted low urinary citrate levels in patients with and without stones. They thought that poor emptying and mucus were more significant factors.

Tumor Formation

A well-recognized complication of ureterosigmoidostomy has been the development of tumors, primarily adenocarcinoma, at the ureterocolonic anastomotic site. In Husmann and Spence's (1990) review of reported tumors after ureterosigmoidostomy, the latency for development of such tumors averaged 26 years and ranged from 3 to 53 years. Adenocarcinomas were the prominent tumors that developed, but benign polyps and other types of carcinoma were also found. Eraklis and Folkman (1978) estimated that the risk for developing such tumors is increased by 7000-fold over age-matched controls after ureterosigmoidostomy. Pettersson et al. (2013) reviewed their experience with 24 patients who had undergone ureterosigmoidostomy from 1944 to 1961; most had eventually been undiverted. Invasive colorectal adenocarcinoma developed in 7 patients, 5 of whom died as a result. The risk for tumor formation was 42 times that of the general Swedish population.

The basis for the increased risk is unknown; however, *N*-nitroso compounds thought to originate from a mixture of urine and feces may be carcinogenic. These compounds have been noted in the urine of patients with conduit diversion and augmentation (Treiger and Marshall, 1991). Husmann and Spence (1990) suggested that those compounds are more likely enhancing agents rather than a lone cause for tumor development. It has been proposed that inflammatory reaction at the anastomotic site may induce growth factor production, which, in turn, increases cellular proliferation. **Filmer and Spencer** (1990) **identified 14 patients who have developed adenocarcinoma in an augmented bladder, and several more have been reported since then;** 9 of those tumors occurred after ileocystoplasty and 5 after colocystoplasty. One study has noted a relatively high incidence of tumor after gastrocystoplasty (Castellan et al., 2007). Experimental work in the rat demonstrated hyperplastic growth in the augmented bladder using all intestinal segments, with no segment showing any particular increased risk (Buson et al., 1993; Kispal et al., 2012; Klee et al., 1990; Little et al., 1994; Spencer et al., 1993). The long latency noted for tumor development after ureterosigmoidostomy suggests that short-term follow-up after augmentation cystoplasty is not adequate to evaluate tumor formation. The earliest reported tumor after augmentation was found only 4 years after cystoplasty (Carr and Hershorn, 1997). **Patients undergoing augmentation cystoplasty should be made aware of a potential increased risk for tumor development.** This increased risk has been confirmed by others but may not be secondary to augmentation, rather thought to be due to an inherent cancer risk associated with the underlying congenital abnormality (Higuchi et al., 2010; Husmann, 2009).

Yearly surveillance of the augmented bladder with endoscopy may eventually be performed; the latency period until such procedures are necessary is not well defined (Higuchi et al., 2011; Vajda et al., 2002). Transitional cell carcinoma, hyperplasia, and dysplasia have also been noted near the anastomosis in humans (Barrington et al., 1997; Gregoire et al., 1993; Soergel et al., 2004). Transitional cell carcinomas associated with augmentation cystoplasty have been aggressive; often the patients have metastatic disease at presentation (Higuchi et al., 2010; Metcalfe et al., 2006). Urothelium adjacent to the anastomosis was demonstrated to be genetically unstable on biopsy in one study (Appanna et al., 2007). Castellan et al. (2012) noted a sobering experience with three cases of fatal adenocarcinoma within the gastric segment among only 29 patients who had undergone gastrocystoplasty. A benign lesion, nephrogenic adenoma, may actually be the most common tumor found after cystoplasty (Franke et al., 2011).

Delayed Spontaneous Bladder Perforation

Another disturbing complication of augmentation cystoplasty is delayed bladder perforation. Patients with spontaneous perforation after augmentation cystoplasty are typically ill with abdominal pain, distention, and fever. Sepsis has been common. Nausea, decreased urine output, and shoulder pain from diaphragmatic irritation have also been noted. Perforations have been found in evaluation of asymptomatic pelvic masses (Pope et al., 1999; Fig. 37.12). **Patients with neurogenic dysfunction often have impaired lower abdominal sensation and are seen later in the course of the illness; severe sepsis and death have occurred.** Patients with perforation after gastrocystoplasty often seek care promptly because of acid irritation. **A high index of suspicion for perforation is necessary. Contrast cystography is diagnostic in most cases** (Bauer et al., 1992; Braverman and Lebowitz, 1991; Rosen and Light, 1991) (see Fig. 37.12). Thorough technique is important to identify as many true positives as possible with cystography (Braverman and Lebowitz, 1991). Some reports have noted a significant false-negative rate on cystography (Pope et al., 1999; Rushton et al., 1988; Sheiner and Kaplan, 1988) and suggested that ultrasonography and computed tomography improve diagnostic accuracy. They recommended that one of those studies be done in any child suspected to have a perforation if the initial cystogram is negative.

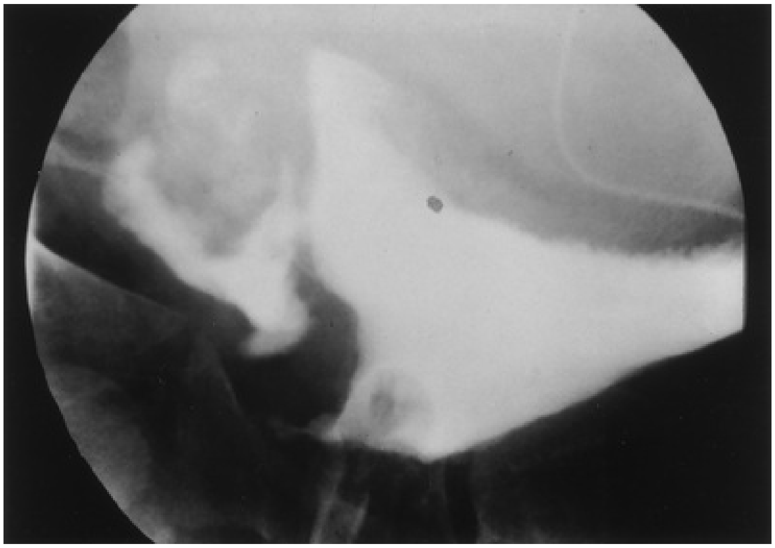

FIG. 37.12 After complete filling, a sagittal view on the cystogram demonstrates a spontaneous bladder perforation on the postdrain view.

Etiology.

The cause of delayed perforations within a bowel segment is unknown. It has been suggested that some perforations may be secondary to traumatic catheterization (Elder et al., 1988; Rushton et al., 1988). Perforation of a bladder not previously augmented has been recognized after CIC (Reisman and Preminger, 1989). It seems unlikely that catheterization trauma is the lone cause in most patients. The location of the perforations has been variable among patients and even in a single patient with multiple perforations. Perforations have occurred in patients after augmentation who did not catheterize at all. Other authors have suggested that trauma to the bowel because of fixed adhesions resulting in sheering forces with emptying and filling may result in perforation (Elder et al., 1988). Transmural infection of the bladder wall has also been proposed as a cause. **Histologic examination of areas of perforation has noted necrosis, vascular congestion, hemorrhage, and hemosiderin deposition compatible with chronic bowel wall ischemia** (Crane et al., 1991). **Chronic overdistention of the bladder may result in such ischemia.** Decreased perfusion in dog bowel used for augmentation can be induced experimentally with high intravesical pressure (Essig et al., 1991); changes were noted more prominently at the antimesenteric border of the bowel. Anderson and Rickwood (1991) have reported perforations occurring in bladders with significant uninhibited contractions after augmentation, as have others (Pope et al., 1998). **High outflow resistance may maintain bladder pressure rather than**

allowing urinary leakage and venting of the pressure, potentially increasing ischemia (Martinez del Castillo et al., 2005). Hyperreflexia alone is likely not a solitary cause of perforation; the complication was not recognized in the era before bowel detubularization and reconfiguration when persistent pressure contractions were more common. **However, once bowel is reconfigured, it may be more prone to ischemia if high pressure does persist.** Failure to perform CIC on a regular basis when needed to empty may exacerbate such issues (DeFoor et al., 2003b; Martinez del Castillo et al., 2005).

The majority of patients who develop perforations after augmentation cystoplasty have had myelodysplasia. The incidence of perforation has been lower in series of patients with other diagnoses requiring bladder reconstruction (Hendren and Hendren, 1990). The role of neurogenic dysfunction in the cause of these perforations is unclear. No matter what the cause, there is likely some field effect on the entire segment. Once a patient has sustained a spontaneous perforation, the chance of recurrence is significant (Hollensbe et al., 1992; Martinez del Castillo et al., 2005), perhaps occurring in one-quarter of patients (Metcalfe et al., 2006). Consideration must eventually be given to removal of the original segment and replacement with another after repeated perforation.

Incidence.

Early postoperative leaks from the bowel-to-bowel or bowel-to-bladder anastomoses after augmentation cystoplasty are rare and represent a technical error or problem with early healing. **Delayed perforations more commonly occur within the bowel segment and represent a problem with long-term storage of urine within an intestinal segment.** There may be no particular increased risk of one intestinal segment over another. At Indiana University, perforations were noted in 43 of 500 patients (8.6%) undergoing cystoplasty (Metcalfe et al., 2006) an average of 4.3 years after augmentation. Analysis of this experience suggested that the use of sigmoid colon was the only significantly increased risk factor. Several other large series of patients with sigmoid cystoplasty have noted a low incidence of delayed perforation (Hendren and Hendren, 1990; Shekarriz et al., 2000; Sidi et al., 1987a). At Children's Hospital (Boston), the incidence of perforation after augmentation was reportedly highest in ileum (9.3%) and less frequent in ileocecal, sigmoid, and gastric segments (Bauer et al., 1992). **With inconsistent differences across multiple large series, it is unlikely that any given enteric segment is at significantly increased risk for perforation and that multiple factors**

influence the risk for the complication. A recent analysis of morbidity in patients undergoing augmentation cystoplasty using the Pediatric Health Information System database showed that the risk of perforation was doubled in those who had bladder outlet procedures (Schlomer and Copp, 2014). In summary, the highest rate of perforation noted was 16.6% in one relatively small series (Martinez del Castillo et al., 2005); however, it is reasonable to present an expected risk of about 9% to patients and families based on experience at Indiana University (Metcalfe et al., 2006).

Treatment.

The standard treatment of spontaneous perforation of the augmented bladder is immediate surgical repair. There are reported series of conservative management for suspected perforation (Slaton and Kropp, 1994). Conservative management including catheter drainage, antibiotics, and serial abdominal examinations was successful in 87% of patients, although only 2 of the 13 patients with suspected ruptures had x-ray documentation unequivocally identifying a perforation. In a more recent study, Lee et al. support a conservative approach in the absence of clinical deterioration, severe peritonitis, and extensive extravasation. Those stable patients were initially managed with maximal bladder drainage and image-guided percutaneous drains placed in loculated fluid collections (Lee et al., 2017). Even patients who do well with conservative management during the acute episode often require eventual surgical intervention (Pope et al., 1999). Such management may be a consideration in a stable patient with sterile urine, but there should be a very low threshold for surgical repair. Most patients with perforations have myelodysplasia and are seen late in the course of the disease because of impaired sensation. Increasing sepsis and death of the patient may result from a delay in diagnosis or treatment.

Pregnancy

Limited information exists regarding the outcome of pregnancy in women who have undergone augmentation cystoplasty. Three issues are raised in the context of pregnancy after bladder reconstruction: how the expanding uterus will affect the pedicle of the reconstruction; how to manage bacteriuria in the setting; and whether cesarean section is necessary in all or some patients.

Hatch et al. (1991) and Schumacher et al. (1997) noted that the mesenteric pedicle to bladder augmentations did not appear to be stretched at the time of cesarean section. In those cases the pedicle was not located near the exposed anterior uterus but deflected laterally. Schilling et al. (1996) recognized similar deflection away from the uterus after urinary diversion but did occasionally find the uterus covered by the vascular pedicle after bladder augmentation. Neither process prevented the rise of the uterus during pregnancy. Those authors speculated that the mesentery underwent changes that enabled deflection or stretch without any adverse effect on circulation. Loss of the augmentation from a mechanical effect on the pedicle from the enlarging uterus has not been reported. The group from Indiana reviewed their experience with 18 pregnancies in 11 women who previously underwent lower urinary tract reconstruction. A high rate of complications were noted and included new or worsening hydronephrosis (87%), of which almost half required percutaneous nephrostomy tube placement. This was noted as the preferred method over indwelling stent to avoid difficult placement because of altered anatomy as well as eliminate the risk for plugging of the stent with mucus. Other reported complications included difficult catheterization in half, in one-third with incontinence, and in two-thirds with UTI. Urology was involved during each cesarean section and this was important as 40% of patients experienced intraoperative complications with the most common being cystotomy during emergent cesarean section. Urinary fistula developed in three patients (Roth et al., 2018).

UTIs may be problematic during pregnancy in women who have undergone urinary reconstruction including bladder augmentation. Ureteral dilation, increased residual urine, and diminished tone to the upper tract may be important risk factors (Hatch et al., 1991; Hill et al., 1990). Asymptomatic bacteriuria is usually treated immediately in pregnant women because of an increased rate of progression to symptomatic infection and pyelonephritis and because of the potentially significant consequences of pyelonephritis. There is little consensus about the role of antibiotics and the risk of asymptomatic bacteriuria in women on CIC after cystoplasty once pregnant (Thomas and Adams, 2009). Antibiotics, if used, must not be teratogenic.

Successful pregnancy with spontaneous vaginal delivery has been observed in some patients with bladder augmentations (Quenneville et al., 2003) and other forms of urinary reconstruction (Asif and Uehling, 1969; Pedlow, 1961). Schumacher et al. (1997) reviewed their experience with pregnancy and delivery in patients who had undergone continent catheterizable ileocecal diversion and found no major complications. This would likely be true for other forms of reconstruction (Wren et al., 2003). Late difficulty with catheterization has been noted with Kock continent ileostomies (Ojerskog et al., 1988) and can occur with any continent abdominal wall stoma (Greenwell et al., 2003).

The need for cesarean section is likely not universal after bladder reconstruction. Flaccid, distensible pelvic tissues, perhaps necessary for progression to spontaneous vaginal delivery, may not be present after extensive pelvic surgery. It is not known if tissues fixed from previous operative repairs can undergo the trauma of delivery and resume the same level of function found before the pregnancy. Our bias would be that woman having undergone extensive bladder neck repair should consider cesarean delivery, particularly if the progression toward spontaneous vaginal delivery is slowed or difficult. Although there are reports of spontaneous vaginal delivery in the presence of an AUS (Creagh et al., 1995; Fishman and Scott, 1993), the presence of such a prosthetic device raises a concern for erosion with a long, difficult delivery.

If cesarean section is required or selected, it is imperative to protect the augmentation or continent stoma and its vascular pedicle. The anterior uterus can typically be exposed atraumatically, although some time and patience may be required to protect the bladder. Such exposure may be more difficult if multiple abdominal stomas are present. The reconstructive urologist familiar with the patient and her anatomy should be present during cesarean section.

Choice of Segment and Approach

Enterocystoplasty improves bladder capacity and compliance in most cases when medical management fails. It is obvious from the previous discussion that there is no one single bowel segment that is perfect for augmentation in all patients. All gastrointestinal segments have been used and continue to be used with good results. Unremitting medical problems are relatively rare after augmentation cystoplasty if used appropriately in well-selected patients. No one bowel segment has a clear advantage over others when all such problems are considered. Patient diagnosis, anatomy, and physiology may suggest that one bowel segment is preferable for a particular patient. Each surgeon interested in augmentation cystoplasty should be familiar with the advantages and disadvantages of each segment in different settings.

In many routine cases, any gastrointestinal segment may be chosen for cystoplasty based purely on the personal preference and familiarity of the surgeon. The surgeon's experience and confidence in using a segment are important. **We believe that no one bowel segment is the best choice in all**

patients and that optimal results are achieved when the bowel segment is chosen based on the needs of the particular patient. The segment must then be used correctly. Ileum is preferred if there is no clear advantage or reason to use another segment. Stomach is reserved for very select children with renal insufficiency and acidosis, short gut syndrome, and heavy irradiation; even then, the potential complications of gastrocystoplasty must be considered (Castellan et al., 2012). Sigmoid cystoplasty is used in select patients without reservation; good results can be expected for most patients with any segment if it is used properly.

The use of laparoscopy, usually with robotic assistance, to achieve augmentation cystoplasty evolved from early work on autoaugmentation to full intracorporeal enterocystoplasty (Ehrlich and Gershman, 1993; Docimo et al., 1995; Gundeti et al., 2008; Lorenzo et al., 2007). Intraoperative times vary greatly among these reports and are related to surgeon experience and inherent patient factors such as prior surgery, working space availability, and whether a pure laparoscopic or robotic-assisted approach is used. Outcomes have been similar to those of open reconstruction in early follow-up (Gundeti et al., 2013; Traxel et al., 2010). Potential advantages of a minimally invasive approach include faster recovery and improved cosmesis (Hasan et al., 2011). Experience with these approaches is already accumulating rapidly, and thorough evaluation will be needed to determine if a minimally invasive approach is cost effective, particularly in the neurogenic population.

A Decreasing Necessity?

Although augmentation cystoplasty works well for most patients who require it, and although work on alternatives to bowel cystoplasty may lower morbidity for the patient, a primary goal for every pediatric urologist is to minimize the number of patients needing cystoplasty. Newer medical regimens, botulinum toxin A injections (Altaweel et al., 2006; Game et al., 2009; Pascali et al., 2011; Schulte-Baukloh et al., 2005; Stoehrer et al., 2009), and neuromodulation may prove effective for some patients who at present do not respond to conservative measures (Aslan and Kogan, 2002; Lansen-Koch et al., 2012). Xiao et al. (2005; Peters et al., 2010) continue to refine an artificial somatic-autonomic reflex pathway in children with neurogenic dysfunction. No matter what the diagnosis, earlier and more aggressive treatment of bladder dysfunction may minimize the insult to the bladder and maximize recovery as well as ultimate bladder function.

Early urodynamic evaluation of boys with posterior urethral valves may identify treatable bladder problems and improve the prognosis from the standpoint of the kidneys and bladder (Casey et al., 2012; Misseri et al., 2002). Grady et al. (2003) suggested that complete primary repair of bladder exstrophy results in early bladder cycling that improves eventual bladder function and decreases the likelihood of augmentation cystoplasty.

With perhaps the most compelling evidence to date, Kaefer et al. (1999a) found that only 17% of patients with hostile neurogenic bladder dysfunction treated immediately on diagnosis required augmentation cystoplasty as compared with 41% of similar patients treated expectantly. Although the series included no collaborative urodynamic data and may be subject to lag time bias, the authors felt that there was a significant difference in the outcomes for the two groups. Because there are no prospective, randomized trials evaluating early evaluation and treatment of pediatric bladder dysfunction, suggestions that expectant treatment may lower the necessity for augmentation cystoplasty (Bauer, 2003; Mitchell, 2003) remain unproven. On early examination, early bladder management had not decreased the rate of augmentation cystoplasty (Lendvay et al., 2006); however, more recent re-evaluation (Schlomer et al., 2013) suggested that augmentation rates have fallen by 25% in the past decade. Critical, prospective evaluation of such treatment is needed and will hopefully demonstrate how to successfully manage these patients. It is likely that such improvements will minimize the need for cystoplasty but not completely remove it (Cain and Rink, 2010).

Improving Quality of Life?

Reconstruction to achieve continence has been assumed to improve health-related quality of life. Early evaluation of small numbers of patients undergoing reconstruction including augmentation cystoplasty does not always show improved status on objective questionnaires compared with preoperative studies or control patients without surgery despite what generally would be considered to be good clinical results (MacNeily et al., 2005; Parekh et al., 2006). Assessment of the social impact of using a catheterizable channel instead of urethra is limited (Kari et al., 2013). Patient-reported scores also do not always correlate with those noted by their parents. Most evaluation of surgical techniques to date has focused on results and complications from the perspective of surgeons. Future evaluation should include objective, patient-reported consideration. Tools to acquire that information must be validated for longitudinal study of these patients and their disease processes.

Key Points: Augmentation Cystoplasty

- Any gastrointestinal segment should be reconfigured and widely anastomosed to the bladder to maximize capacity and compliance.
- Failures to achieve adequate compliance are rare (5% to 10%) and are usually related to rhythmic pressure contractions.
- Gastrointestinal effects are rare, although chronic diarrhea may occur if the ileocecal segment is used in the neurogenic population.
- Ammonium resorption can cause metabolic acidosis, particularly among patients with renal insufficiency.
- Bacteriuria is common after cystoplasty and does not always require treatment.
- Bladder calculi occur in 10% to 30% of patients after augmentation.
- Aggressive adenocarcinomas have been reported as early as 4 years after augmentation but thus far have not occurred with the frequency noted after ureterosigmoidostomy.
- Delayed perforation of the bowel segment can be expected in 5% of patients after augmentation. It has occurred most frequently in colonic segments used in the neurogenic population.
- Good early care for underlying bladder dysfunction may lower the need for augmentation cystoplasty.

Ileovesicostomy

This alternative approach certainly has a role in the management of pediatric patients with neurogenic bladder. Because of its incontinent nature, proper counseling and education of parents and older patients is necessary to achieve the desired outcome. This technique may be best for those patients who are mentally, physically, or socially unable to catheterize via a continent channel. Other indications may include a hyperreflexic detrusor and small bladder capacity (Ching et al., 2014). The main advantage over a regular vesicostomy is the ability to be dry via the urethra while using a bag appliance to avoid constant urinary leakage and the need for diapers. Advantages over continent diversion includes a low-pressure reservoir, thus greatly lowering risk for perforation, potential avoidance of sphincteric surgery, lack of catheterization, and possibility of conversion to continent diversion if desired. Shared risks include risk of bowel related complications, stomal stenosis or prolapse, formation of stones, UTIs, and upper tract deterioration.

Technique and Results

The technique involves the isolation and use of a 10- to 15-cm channel of small intestine, similar to that employed for an ileal conduit, which is then anastomosed in an isoperistaltic fashion to the dome of the native bladder and brought out as a rosebud stoma on the skin. This acts as a passive channel for urine to flow down the path of least resistance. Outcomes in the pediatric population are not as well documented as those in the adult population. Ching et al. reported the first known outcome study in pediatric patients highlighting similar complication rates of postoperative UTI, stomal issues, wound infection, bowel-related issues, and need for additional postoperative procedures as in the adult literature (Ching et al., 2014). This was a small, retrospective study in a carefully selected group of patients, so long-term complications could not be assessed. This is important as length of follow-up and patient body mass index have been directly associated with number of complications. Obesity is common among children with spina bifida during the transition into adulthood. Tan et al. noted the association of obesity with the need for additional procedures or reoperations in 27/50 patients (Tan et al., 2008). Based on this data, these patients must be regularly followed to avoid potentially devastating consequences to the upper tracts.

Key Point: Ileovesicostomy

- Ileovesicostomy is a viable option for a carefully selected group of patients but carries increased risk for long-term complications if not followed appropriately.

Alternatives to Gastrointestinal Cystoplasty

Largely because of the complications just reviewed, alternative methods that can achieve a large-capacity, compliant reservoir remain attractive. Efforts have covered the spectrum from synthetic materials and autologous grafts through creation of a bladder diverticulum (autoaugmentation) to various forms of neural stimulation. **Some of these alternatives appear to hold promise, but none have stood the test of time in comparison with intestinal cystoplasty.**

An ideal tissue for increasing capacity and improving compliance would have transitional epithelium to be relatively impermeable and avoid metabolic changes. The lining would also not produce mucus and would carry no increased potential for tumor development. Two such alternative procedures are ureterocystoplasty and autoaugmentation. With ureterocystoplasty, there is good muscle backing to transitional epithelium, whereas collagen eventually backs the transitional mucosa of an autoaugmentation.

Ureterocystoplasty

In patients with posterior urethral valves, unilateral reflux may behave as a pop-off valve to lower intravesical pressures (Hoover and Duckett, 1982; Kaefer et al., 1995; Rittenberg et al., 1988). **It was a logical extension to use ureteral tissue in that setting to augment the bladder.**

Technique.

Ureterocystoplasty may be performed through a midline, intraperitoneal incision. This incision provides access to the intestine should mobilization of the ureter for augmentation be unsatisfactory. **Bellinger** (1993), **Dewan et al.** (1994), **and Reinberg et al.** (1995) **have shown that ureterocystoplasty can be done through two incisions, remaining completely extraperitoneal.** The general technique is the same. A standard nephrectomy is performed with great care to preserve the renal pelvic and upper ureteral blood supply. All adventitia and periureteral tissue are swept from the peritoneum toward the ureter during mobilization to protect the ureteral blood supply. Proximally, this blood supply typically arises medially. As the ureter enters the true pelvis, the blood supply arises posterior and laterally. After mobilization of the ureter into the pelvis, the bladder is opened in the sagittal plane. Posteriorly, this incision has typically been carried off-center directly into and through the ureteral orifice of the ureter used for cystoplasty. The ureter is *not* detached from the bladder but is opened longitudinally along its entire length, taking care to avoid its main blood supply (Fig. 37.13). The incision in the bladder and distal ureter should avoid branches of the superior vesical artery, which serve as an important blood supply. The ureter is folded on itself, and the ureter-to-ureter and ureter-to-bladder anastomosis is performed with running absorbable suture. A suprapubic tube is left indwelling through the native bladder for 3 weeks during healing. After cystography documents the absence of leakage, CIC is started. Any patient attempting to void must prove that he or she can empty adequately through a check of postvoid residuals.

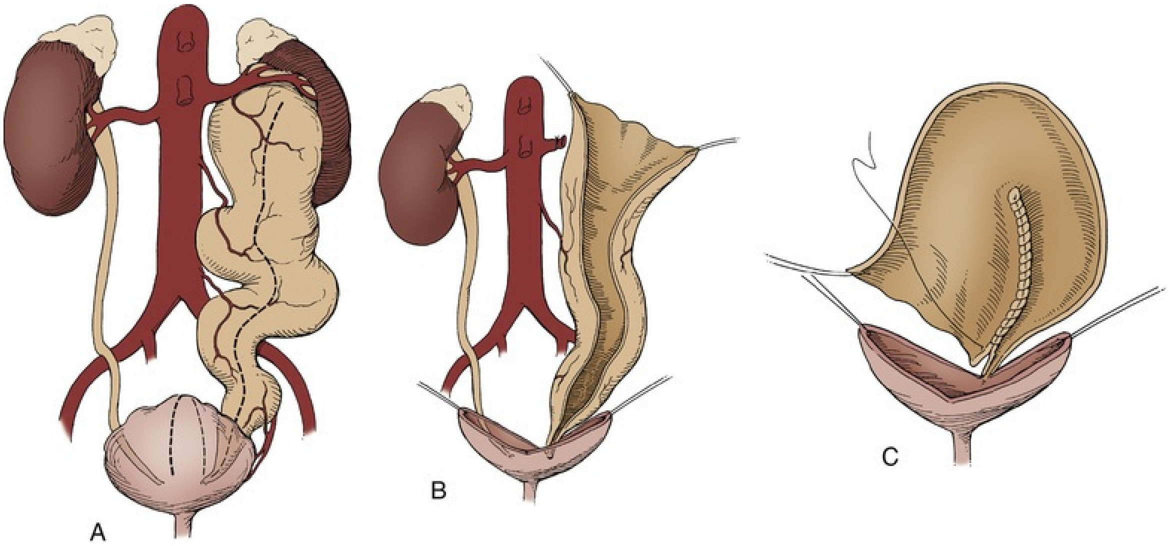

FIG. 37.13 Ureterocystoplasty. (A) After nephrectomy, the bladder is bivalved, with the posterior aspect of the incision carried off the midline to enter the ureteral orifice. The ureter is not detached from the bladder. (B) The ureter is opened opposite its main blood supply. (C) The ureter is reconfigured as in intestinal cystoplasty before anastomosis to the bladder.

Alternatively, the bladder incision can be stopped approximately 2 cm from the orifice, and a similar length of distal ureter left in situ and intact without incision. The resulting small loop of intact ureter does not create clinical problems or adversely affect the end volume in a significant manner (Adams et al., 1998). This modification of technique is easier and may be safer in that it avoids potential injury to the blood supply of the ureter.

Results.

Early experience with the procedure noted that the entire renal pelvis could be preserved, allowing more tissue for cystoplasty (Churchill et al., 1993; Landau et al., 1994; McKenna and Bauer, 1995; Reinberg et al., 1995). As with intestinal cystoplasty, folding the ureter into a more spheric configuration maximizes the volume to be achieved. If a massively dilated ureter drains a functioning kidney, the distal ureter may be used for augmentation, with the proximal ureter either reimplanted into the bladder or anastomosed to the contralateral ureter (Bellinger, 1993). Numerous series have reported good results after augmentation using ureter. The upper tracts have remained stable or improved in almost all patients. Complications have been uncommon. Landau et al. (1994) compared age-matched and diagnosis-matched children undergoing ureterocystoplasty or ileocystoplasty. **The total mean bladder capacity was 470 mL in the ureterocystoplasty group and 381 in the ileocystoplasty group. Bladder volumes at 30 cm H_2O were 413 mL and 380 mL after ureterocystoplasty and ileocystoplasty, respectively.** Ureter effectively enhanced volume and compliance. There was one failure in the group, which occurred in a child in whom the distal ureter did not provide enough volume. Work has shown that one dilated ureter typically is enough for cystoplasty (Kajbafzadeh et al., 2010; Zubieta et al., 1999).

The main disadvantage to ureterocystoplasty is the limited patient population with a nonfunctioning kidney draining into a megaureter. McKenna and Bauer (1995) reported the use of a normal-sized ureter. The ultimate success of ureterocystoplasty using normal-sized ureter requires further follow-up, particularly because Gonzalez (1999) stated that in one-quarter of his patients with posterior urethral valves, ureterocystoplasty with a dilated ureter has failed because of their huge urinary volume. Husmann et al. (2004) noted even worse results if the ureter used was less than 1.5 cm in diameter. Patients can have a good long-term result with ureterocystoplasty but must be carefully selected (Johal et al., 2008). Atala et al. (1994) presented an experimental technique to slowly dilate a normal ureter for later use. Work continued in porcine models (Desai et al., 2003; Stifelman et al., 1998); however, the principle has not yet proven to be clinically feasible.

Autoaugmentation

Techniques and Results.

Cartwright and Snow (1989a, 1989b) described a method to improve bladder compliance and capacity through use of native urothelial tissue. In their procedure, known as *autoaugmentation*, the detrusor muscle was excised over the dome of the bladder, leaving the mucosa intact to protrude as a wide-mouthed diverticulum. Initially they made a midline incision through the bladder muscle (Fig. 37.14A). With the bladder distended with saline so that mucosa bulged from the incision, the muscle was then mobilized and excised laterally in each direction (Fig. 37.14B). The lateral edges of the detrusor muscle were then secured to the psoas muscle bilaterally to prevent collapse of the diverticulum (Fig. 37.14C). Their early experience noted improved compliance in most and increased capacity in some patients (Cartwright and Snow, 1989a).

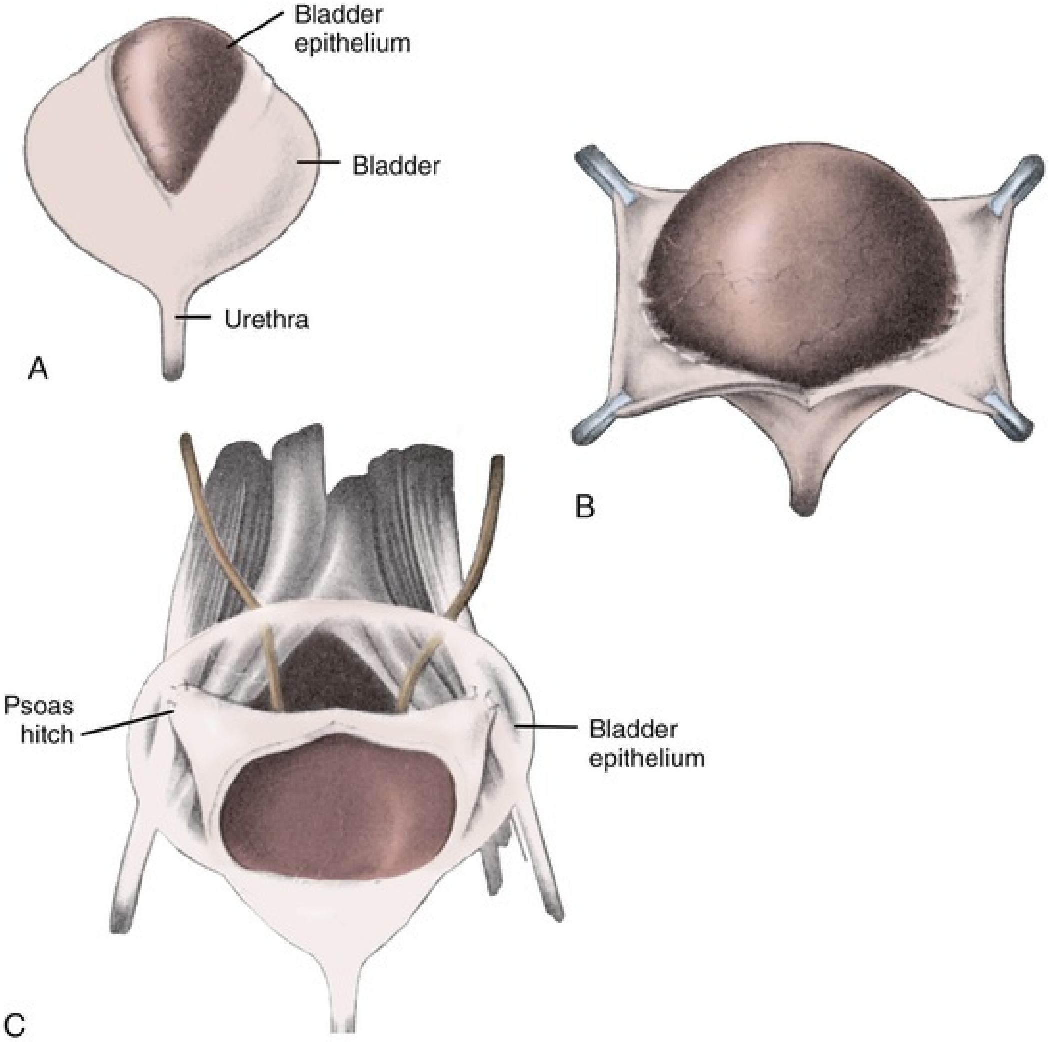

FIG. 37.14 Autoaugmentation. (A) The detrusor is incised. (B) Detrusor is stripped and excised from mucosa. (C) The detrusor muscle is anchored bilaterally so that the mucosa bulges with bladder filling. (From Cartwright PC, Snow BW: Bladder autoaugmentation: early clinical experience. *J Urol* 142:505, 1989.)

This procedure has since been modified by a number of surgeons, each applying a different name for the procedure depending on whether the detrusor muscle was simply incised or was excised to create the

diverticulum. In an effort to determine if incision or excision provided superior results, Johnson et al. (1994) performed 16 vesicomyotomies and 16 vesicomyectomies in rabbits after previously reducing bladder capacity. Functional bladder capacity in the animals increased by 43.5%, and there was no statistical difference between the two techniques. They then performed vesicomyotomies (incision) in 12 patients with neurogenic bladder dysfunction and demonstrated a mean increase in capacity of 40% (Stothers et al., 1994). They concluded that detrusor excision offered no advantage over incision. All patients demonstrated some increase in capacity (15% to 70%), and no patient in early follow-up clinically deteriorated and required enterocystoplasty.

Detrusorectomy, leaving a small cap of muscle at the dome through which a suprapubic tube can be placed, was proposed by Landa and Moorhead (1994). **They were concerned that although these procedures usually improve compliance, increase in volume is "modest at best," a concern shared by others** (Snow and Cartwright, 1996; Cartwright and Snow, personal communication, 1998). In a report of 12 detrusorectomies, 5 patients were considered to have excellent results, 2 to have acceptable results, and 1 was lost to follow-up. Failures occurred in 4 patients, of whom 3 underwent conventional augmentation (Landa and Moorhead, 1994). In a combined series at those two institutions, only 52% of patients had a good result with autoaugmentation, whereas 20% had a poor outcome (Snow and Cartwright, 1996). Reoperative enterocystoplasty was not hampered by the prior detrusorectomy. The urothelial diverticulum at the time of augmentation cystoplasty was noted to be thick and fibrous, similar to a leather bag.

In general, complications from the procedures are uncommon. Perforation, a major concern after intestinal cystoplasty, has not been reported. Inadvertent opening of the mucosa during the procedure can make subsequent mobilization more difficult and may promote prolonged postoperative extravasation. Such extravasation usually stops with bladder drainage (Landa and Moorhead, 1994: Stothers et al., 1994). Prolonged drainage, however, may result in compromised results because of collapse of the diverticulum. Rocha et al. (2011) suggested that early use of a silicone balloon to maintain distention may improve results. If concomitant ureteral reimplantation or bladder neck surgery is necessary, various authors have recommended that it be done first and the bladder then closed before detrusorectomy (Stothers et al., 1994).

Ehrlich and Gershman (1993) first reported laparoscopic myotomy (incision). A laparoscopic approach uses a smaller incision and perhaps shortens postoperative hospitalization; it may allow effective fixation of the detrusor muscle in an open fashion to make good bulging more difficult.

Concerns.

The main disadvantage of autoaugmentation is a limited increase in bladder capacity such that adequate preoperative volume may be the most important predictor of success (Landa and Moorhead, 1994). If the maximum capacity and the volume of urine held at 40 cm H_2O are similar, the patient may be better served by immediate intestinal cystoplasty. Some patients have demonstrated clinical improvement after these procedures without a significant change in urodynamics. The reason for improvement in that setting is unknown.

In most series of autoaugmentation, no matter what the technique, occasional patients have been noted or concern has existed at the time of the initial procedure that adequate expansion was not achieved. In many series, the autoaugmentation procedure, regardless of technique, has not provided adequate increase in bladder capacity, leading surgeons to proceed with formal enterocystoplasty instead. In most such cases it was elected to proceed with enterocystoplasty immediately at the time (Landa and Moorhead, 1994). The patient and surgeon must be prepared for such an event on occasion. Stoehrer's group (1999) as well as Leng et al. (1999) reported good results with the technique among patients with hyperreflexia. In terms of capacity, even if adequate expansion is achieved initially, there is concern that any improvement may not persist long term (Dewan et al., 1994). In animals, the surface area of the autoaugmentation site was noted to decrease approximately 50% by 12 weeks. Progressive thickening and contracture of the site have been noted because of collagenous infiltrate (Johnson et al., 1994). Milam (personal communication, 2000) noted that almost one-half of his adult patients with hyperreflexia who had a good early result after autoaugmentation failed with longer follow-up. Similar delayed failures have been noted in pediatric patients (Lindley et al., 2003), including one series with very poor results (MacNeily et al., 2003). To the contrary, Hansen et al. (2013) found that early decreases in capacity improvement may reverse with longer follow-up.

At this point, autoaugmentation should likely be considered only in patients who have reasonable capacity but refractory uninhibited contractions. Those same patients may respond to Botox injection or neural stimulation. **If a significant increase in capacity is needed, autoaugmentation may not be definitive.**

Seromuscular Enterocystoplasty

Based on concerns about collagen deposition and contraction around autoaugmentation, efforts have been made to cover the bulging urothelium with demucosalized enteric segments. Use of bowel segments stripped of their mucosa within the bladder is not new. If exposed submucosa was left facing the bladder lumen, re-epithelialization with urothelium was noted in animals. Despite re-epithelization, patch contracture often occurred (Oesch, 1988; Salle et al., 1990). Several series evaluated demucosalized augmentation in humans, with care taken to preserve the submucosa. Some encouraging results were noted (Dayanc et al., 1999; de Badiola et al., 1999; Lima et al., 1998; Lima et al., 2004), although regrowth of metaplastic enteric mucosa was found in the second study. Early placement of a silicone balloon or mold may help prevent contracture (Lima et al., 2004).

Technique and Results.

To avoid contracture, a combination of autoaugmentation after detrusorectomy and coverage with a demucosalized enteric segment has now been used. Buson et al. (1994) used reconfigured, demucosalized sigmoid colon placed over the urothelium (seromuscular colocystoplasty lined with urothelium [SCLU]). They, and others, noted that the intestinal submucosa should be preserved to avoid contracture (Buson et al., 1994; Vates et al., 1997; Fig. 37.15). This procedure has been performed clinically with early reports of good results in most patients (Gonzalez et al., 1994). Endoscopic biopsy of the segments has been interesting. Of 10 biopsy specimens, 1 was noted to contain urothelium with islands of colonic mucosa, whereas 2 others were found to contain only colonic mucosa. Removal of all of the enteric mucosa is important when using sigmoid to prevent mucoceles or overgrowth of intestinal mucosa (Gonzalez et al., 1994; Lutz and Frey, 1994). Dewan et al. (1997) felt preservation of the submucosa eventually promoted regrowth of bowel mucosa. The interaction of the two different tissues will be interesting to follow. The long-term effects on the urothelium by the seromuscular segment and vice versa are unknown. Work has shown that persistent transitional lining will protect from metabolic problems and mucus production (Denes et al., 1997).

FIG. 37.15 Seromuscular enterocystoplasty with use of sigmoid colon. Detrusor incision is performed as in autoaugmentation; however, the bulging mucosa is covered with a demucosalized segment of sigmoid colon. (From Buson H, Manivel JC, Dayanc M, et al.: Seromuscular colocystoplasty lined with urothelium: experimental study. *Urology* 44:745, 1994.)

These procedures are technically more demanding than simple augmentation or autoaugmentation and are associated with more blood loss and a longer operative time (Gonzalez et al., 1994; Horowitz et al., 1995). Increased bleeding is particularly true when stomach is used. These urothelial-lined, seromuscular augmentations are theoretically attractive. Thus far, the failure and reoperation rate after such procedures remains higher than that noted for standard enterocystoplasty at most centers (Carr et al., 1999; Jung et al., 2012; Shekarriz et al., 2000; Vates et al., 1997). The best results have been reported with use of colon and a mold to minimize contracture (Lima et al., 2008). They noted bladder capacity to rise from a median of 73 mL to 250 mL, an increase of 349%. Only 12.6% of patients were thought to have failed after nonsecretory intestine-cystoplasty (Lima et al., 2008).

Bladder Regeneration

Efforts to find alternatives to intestinal cystoplasty in the 1950s included the use of alloplastic materials for bladder substitution (Gleeson and Griffith, 1992; Kanematsu et al., 2007; Kropp et al., 1995b, 2004; Lewis and Cheng, 2007; Roth et al., 2011; Yamzon et al., 2008). Early research efforts met with very limited success because of foreign body complications but provided a foundation for regenerative medicine. This led to focus on biodegradable, collagen-rich tissues serving as scaffold with and without cell "seeding" for bladder regeneration (Atala et al., 1992; Fishman et al., 1987; Harrington et al., 2008; Kambic et al., 1992; Kelami, 1971; Kropp et al., 1995a; Zhang et al., 2004). Atala et al. (2006) provided the first reported data regarding use of a seeded biodegradable construct for augmentation in the neurogenic population. This work led to an industry-supported prospective multi-institution investigation using a neobladder construct (Joseph et al., 2009). Unfortunately, compliance improved in only 4 patients after 12 months and in 5 at 36 months, but in none to a clinically or statistically significant degree. Capacity did not improve either (Joseph et al., 2014).

Using autologous tissue from a neuropathic source may result in lower yield of cells for use (Subramaniam et al., 2011) or could potentiate growth of abnormal tissue; an alternate cell source for regenerative tissue such as stem cells might circumvent those concerns. The use of stem cells carries its own set of obstacles (Aboushwareb and Atala, 2008; Aitken and Bägli, 2009; Chen et al., 2011; Soler et al., 2009). Further investigation into the clinical applicability of regenerative tissue engineering is required, but this technology could alter the field of reconstructive bladder surgery.

Key Points: Alternatives to Gastrointestinal Cystoplasty

- Ureterocystoplasty avoids complications associated with bowel segments but may not provide adequate volume if the ureter is not remarkably dilated.
- Autoaugmentation seldom adds significant capacity and may not always improve compliance long term.

Continent Urinary Diversion

The frequency with which continent urinary diversion is performed in children depends on the definition of continent diversion. Tumors resulting in cystectomy among children are much less common than in adults. Thus, in the setting cystectomy for cancer or severe congenital abnormality of the bladder, a pure continent urinary diversion, such as a Kock or Indiana pouch, may be performed. Very good results with continent diversion in children have been achieved, equivalent to those reported in adults (Stein et al., 2005). Orthotopic neobladders in children are performed very infrequently because neurogenic or anatomic problems at the outlet prevent spontaneous voiding in many cases. Occasionally a child with neurogenic dysfunction may be a candidate for orthotopic bladder substitution (Stein et al., 2000, 2005), but it is not clear how many of those patients with neurogenic dysfunction can be expected to void adequately.

Some authors have defined combinations of bladder augmentation, continent abdominal wall stoma, and some procedure at the outlet as continent diversions (Kaefer et al., 1997b). Division and closure of the bladder neck to prevent incontinence per native urethra has typically meant inclusion. These procedures typically have been performed in complex patients with multiple problems that must be addressed, often after numerous previous surgeries.

Considerations

The amount of bowel used in continent urinary diversion may vary depending on the patient. Total bladder replacement requires much more intestine than simple augmentation. Typically a 40-cm segment of small bowel is used for an ileal reservoir in a Kock pouch compared with the 20 cm often used for augmentation. Likewise, the entire right colon with the hepatic flexure may be used in an Indiana pouch, whereas only 15 to 20 cm of colon are needed for colocystoplasty. Because of the potential morbidity associated with use of a larger intestinal segment, the native bladder is often used in children if it provides any significant volume. To do so, however, may require repair of the outlet if outflow resistance is low.

Imbrication of the ileocecal valve and terminal ileum has proven to be a simple and reliable means for construction of an effective efferent limb in continent diversion among adults and children. Despite reports to the contrary in select patients (Husmann and Cain, 1999), concern about fecal incontinence secondary to use of the ileocecal valve persists for patients with neurogenic dysfunction. The flap valve continence mechanism provides numerous alternatives for those surgeons with such concerns in continent diversion. Good results achieved with use of the appendix or tapered intestinal segments have led to their increased use.

Whereas maintenance of the native urethra for catheterization is ideal, it may not be appropriate or possible in all individuals. Urethras after reconstructive bladder neck procedures are often subject to difficulty with catheterization. **Children with neurogenic sphincter incompetence may have associated neurologic limitations that prevent easy access to the native urethra. This is particularly true for the wheelchair-bound child. For children without neurologic deficits, normal sensation in the native urethra can prevent compliance with a routine catheterization schedule because of discomfort. For these reasons, a continent catheterizable stoma provides an adequate and sometimes a more reliably useful alternative.**

Continence Mechanisms and Catheterizable Stoma

Ureterosigmoidostomy and Its Variants

Ureterosigmoidostomy can be an effective form of continent urinary diversion in some patients. Its advantage is the spontaneous evacuation of urine with stool. The significant complications of hyperchloremic acidosis, infection, hydronephrosis, and colonic malignancies have led to disfavor and disuse, particularly in the United States. **Although good results with standard ureterosigmoidostomy have been reported in some children, the procedure is rarely performed as originally described. The morbidity of acidosis and upper tract changes may increase with time, making those complications particularly worrisome for children with a long life expectancy. The significant risk of adenocarcinoma commits the patients to a lifetime of close surveillance for an avoidable tumor.** It is unlikely that ureterosigmoidostomy, as classically described, will regain acceptance for children.

Several modifications of ureterosigmoidostomy have been developed in an attempt to decrease the significant complication rate. **The most basic of the modifications is the sigma rectum or the Mainz II pouch.** The colon is incised along the antimesenteric border for 6 cm proximal and distal to the rectosigmoid junction. The ureters are implanted in an antirefluxing fashion, and that portion of colon is then reconfigured and closed. This is done to create a rectosigmoid reservoir of lower pressure to protect the upper tracts. The Mainz II pouch has been used in children with bladder exstrophy (Stein et al., 1997a). Continence in appropriately selected patients is good, although acidosis is still a significant problem because of exposure of the entire colon to urine (Fisch et al., 1996; Gerharz et al., 1999; Mingin et al., 1999b). The risk for development of adenocarcinoma is unaltered with this technique. Long-term follow-up is necessary to determine if the reconfiguration of the sigmoid in the area of ureteral implantation is truly effective for protection of the upper tracts. Stricture at the ureterocolonic anastomosis has been the most common complication in relatively short follow-up (Fisch et al., 1996).

In an effort to control the amount of colon to which urine is exposed, Kock et al. (1988) **described creation of a colorectal valve to confine urine distally.** The intussuscepted nipple valve was stabilized with permanent staples. The distal rectal segment was opened and patched with ileum to lower pressure. With short-term follow-up, the valve was effective in that no necessity for sodium bicarbonate or potassium citrate therapy was noted (Kock et al., 1988; Mahran et al., 1999). Urodynamic evaluation revealed low pressure in the rectal reservoir (Kock et al., 1988), but long-term follow-up in children is needed to see if it is truly less morbid in terms of infection and upper tract deterioration.

If placement of a colorectal valve avoids most complications of metabolic acidosis from ureterosigmoidostomy and creation of a reservoir with lower pressure better protects the upper tracts, the last remaining major concern about ureterosigmoidostomy is tumor development. The concern is significant; of 94 children followed in Boston after ureterosigmoidostomy, 7 developed adenocarcinoma, of whom 4 died of the tumor (Rink and Retik, 1991). Kock et al. (1988), followed by Skinner et al. (1989), used a hemi-Kock pouch to augment the distal rectal segment. A colorectal valve was created to isolate urine to the distal colonic reservoir. The afferent nipple valve kept stool away from the ureteroileal anastomoses, perhaps lowering the risk for tumor development. Simoneau and Skinner (1995) reported their results with the procedure in 15 patients, including 4 children. Their complication rate, both early and late, was relatively high. This is not surprising, considering the relatively complex nature of the procedure. They did think that pediatric patients were better suited for the procedure. Rink and Retik (1991) suggested that the rectum could be augmented with a nonrefluxing ileocecal conduit in a similar fashion.

Before any variant of ureterosigmoidostomy is considered, competence of the anal sphincter must be ensured. Tests used to assess sphincter integrity include manometry, electromyography, and practical evaluation of the ability to retain an oatmeal enema in the upright position for a period of time without soilage. Incontinence of a mixture of stool and urine results in foul soilage and must be avoided. Most patients with neurogenic dysfunction who are incapable of fecal continence in the presence of diarrhea are not candidates for these procedures. Procedures that separate the fecal and urinary streams within the rectal sphincter have been described but have not been widely used in children.

Nipple Valves

The most extensive experience with nipple valves used to achieve urinary continence has been with the Kock pouch. Skinner et al. (1989) made a series of modifications to aid in maintenance of the efferent nipple. Despite experience and use of these modifications, a failure rate of 15% or higher can be expected (Benson and Olsson, 1998; Fig. 37.16A). Several authors have reported a reoperative rate of approximately 33% with the Kock pouch, most frequently related to the efferent nipple (deKernion et al., 1985; Waters et al., 1987). Equivalent results with the nipple valve and a Kock pouch have been achieved in children (Abd-El-Gawad et al., 1999; Hanna and Bloiso, 1987; Kaefer et al., 1997b; Skinner et al., 1988). The last report noted a significant incidence of hyperchloremic acidosis and new hydronephrosis, although those complications were likely related to the complex nature of the patients rather than the particular continent diversion used.

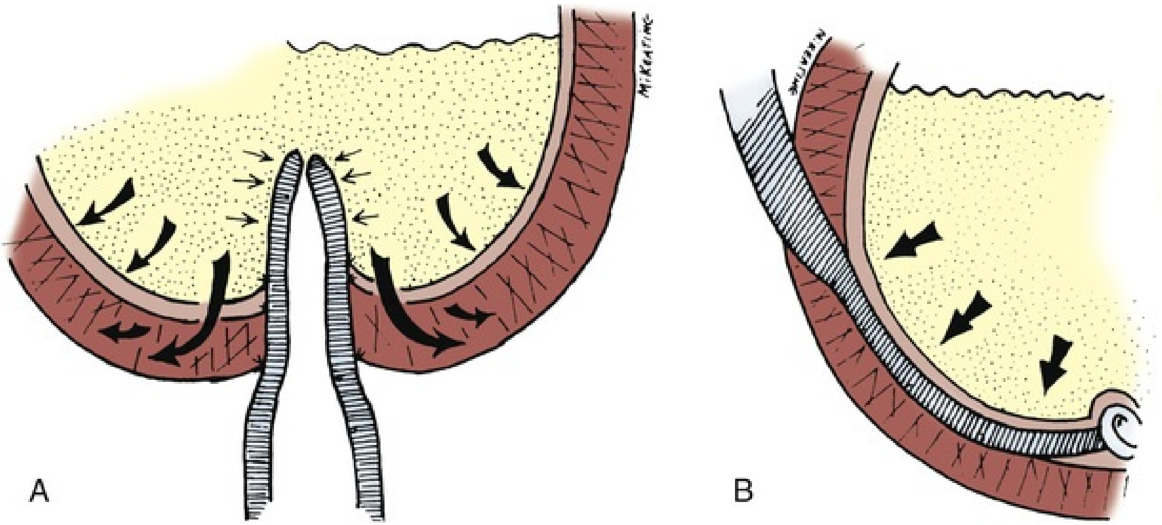

FIG. 37.16 Continence mechanisms. (A) The same pressures that create continence tend to efface nipple valves. (B) This is not true of flap valves, which have been more reliable in pediatric reconstruction.

Intussuscepted nipple valves have also been used with colonic and ileocolonic reservoirs, particularly the Mainz I pouch. Evolution of the nipple valve in the Mainz pouch also occurred over time (Hohenfellner et al., 1990; Stein et al., 1995; Thuroff et al., 1986, 1988). Most recently, the intussuscepted ileum was fixed with staples, passed through the intact ileocecal valve, and fixed again. Much as with the Kock pouch, the incidence of incontinence decreased with experience and modifications. The Mainz I pouch has been used in children with good results and low rates of incontinence using the latest modifications (Stein et al., 1995, 1997a; Stein et al., 2000; Steiner et al., 1998). Maintenance of normal upper tracts has been good, and metabolic problems rare (Stein et al., 1997b).

Flap Valves and the Mitrofanoff Principle

Mitrofanoff (1980) described a continence mechanism using the appendix and ureter to create a flap valve. He recognized that any tubular structure could be implanted effectively into a low-pressure reservoir. This continence mechanism circumvents many of the secondary potential complications associated with harvesting the ileocecal valve or using other gastrointestinal segments.

The foundation for the success of the Mitrofanoff principle is based on creating a submucosal tunnel for a supple, small-diameter conduit. As the reservoir fills, the rise in intravesical pressure is transmitted through the epithelium and to the implanted conduit, coapting its lumen (Fig. 37.16B). The **appendix is an ideal tubular structure that can be safely removed from the**

gastrointestinal tract without significant morbidity. The small caliber of the appendix facilitates creation of a short functional tunnel within the bladder wall. Experience has shown that continence can be achieved with only a 2-cm appendiceal tunnel (Kaefer and Retik, 1997). Whether implanted into a bowel segment or native bladder, the appendix has been used as an efferent limb with very good results (Cain et al., 1999; Jayanthi et al., 1995; Kaefer et al., 1997b; Mollard et al., 1997; VanderBrink et al., 2011). The appendix has been particularly useful in children because it is relatively longer and the abdominal wall generally thinner. The flap valve is likely the most reliable of all of the surgically constructed continence mechanisms. Some patients with a flap valve almost never leak per stoma; this potentially puts them at risk for upper tract deterioration or spontaneous rupture of the bladder or reservoir if catheterization is not routinely performed.

If the appendix is used in situ as a continence mechanism in a continent urinary reservoir, the reservoir by necessity will include the right colon. Duckett and Snyder (1986, 1987) used the right colon and appendix with good results in children. The mesoappendix, in most cases, allows mobilization of the appendix for use in the native bladder or virtually any reservoir.

Technique.

In most children good exposure to the appendix and reservoir can be achieved through a low midline or a transverse incision. On occasion, the cecum may be high in the abdomen, and mobilization of the ascending colon along the line of Toldt may be required to gain access to the appendix and its mesentery. Cadeddu and Docimo (1999) have used laparoscopy to aid in the mobilization of the ascending colon and cecum. Once the cecum has been mobilized, the base of the appendix is amputated, leaving a small cuff of cecum with the appendix. Use of the cecal cuff at the stoma may decrease the risk of stenosis. The cecum is closed in a fashion similar to an open appendectomy. If the length of the appendix is marginal, a greater portion of the cecum can be harvested to effectively increase the functional length of the appendix (Bruce and McRoberts, 1998; Cromie et al., 1991).

After harvesting, a location is selected for implantation of the appendix into the bladder. The location is based on the length of the appendix, the mobility of the bladder, and the location for the appendiceal stoma. Typically the distal end of the appendix is tunneled into a posterolateral position within the bladder (see Fig. 37.17), although an anterior site may be useful as well depending on anatomy. Creating a tunnel is easily done whether the bladder is opened or not (VanderBrink et al., 2011). Successful continence has also been achieved by developing an extravesical trough with or without a serosal base and then covering the channel with laterally mobilized serosa (Baradaran et al., 2013; Elshal et al., 2011).

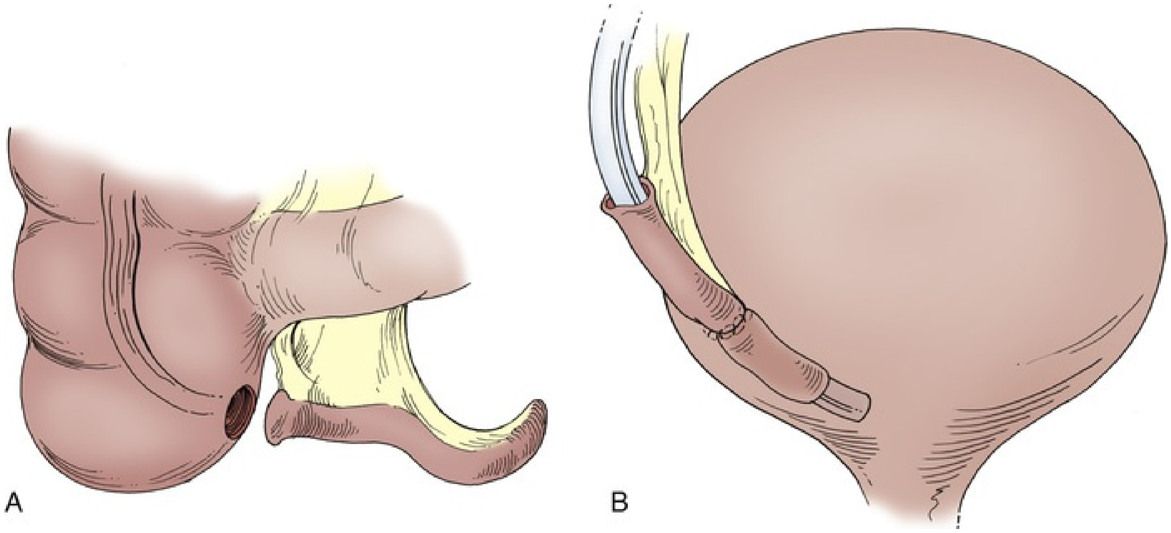

FIG. 37.17 Appendicovesicostomy. (A) The appendix is harvested with a cuff of cecum on a wide pedicle based on the appendiceal artery. A flap of cecum can be harvested in continuity with the appendix and tubularized to increase the length. (B) The distal appendix is tunneled into the bladder to provide continence after the end is amputated. The proximal end of the appendix, the cecal cuff, is brought to the umbilicus or right lower quadrant as a catheterizable stoma.

The base of the appendix is brought to the abdominal wall in a location chosen preoperatively to suit the patient. It should be brought up to reach the skin without tension. Care must be taken not to twist the pedicle or occlude it as it passes through the abdominal wall fascia. The base of the appendix can often be hidden within the umbilicus, which allows for elimination of a small but obvious abdominal stoma. Because of the small circular diameter of the appendiceal base, stomal stenosis is common, and techniques have been described to prevent this problem. Various flaps have been described as a method for avoiding stomal stenosis (Berrettini et al., 2008; Frane-Guimond et al., 2006; Kajbafzadeh et al., 1995; Kaefer and Retik, 1997; Keating et al., 1993; Landau et al., 2008). Weikert et al. (2012) described a rotational umbilical flap to enhance mobility and decrease tension when anastomosing to a channel with a short mesentery.

Regardless of the technique, stomal stenosis remains the most common of complications. Chronic nighttime use of a stent through the channel may decrease that risk (Mickelson et al., 2009).

For prevention of kinking and problems with catheterization, it is advisable to maintain as short a conduit as possible. Securing the appendix and bladder wall to the peritoneum beneath the fascia will help diminish the problem of conduit kinking with reservoir filling. When appendix or any catheterizable stoma is used, it is advisable to repeatedly catheterize the channel after each step in reconstruction to confirm easy passage. If the catheter does not pass easily into the reservoir, the prior step must be revised. Problems with catheterization by the surgeon during the operative procedure usually result in more difficulty for the patient afterward. It is also beneficial to catheterize at variable reservoir volumes to confirm proper fixation of the reservoir and the absence of any kinking. The basic principles used for open reconstruction of a catheterizable channel can be used laparoscopically and with robotic assistance to achieve the same level of success (Badawy et al., 2013; Famakinwa et al., 2013; Hsu and Shortliffe, 2004; Rey et al., 2013; Wille et al., 2011).

A 6-Fr to 12-Fr stent is typically left for 10 to 14 days within the efferent catheterizable channel during the healing process. It is then advisable for the surgeon to personally catheterize the efferent limb before the patient or family members do so. Catheterization should be repeated at least every 4 hours during the day for reservoir drainage, maintenance of patency, and minimalization of the risk of stomal stenosis.

The appendix may not be available for use in all patients because of previous appendectomy, its location or length, congenital absence, involvement with adhesions, or its use for continence enemas. Histologic abnormalities of the appendix have been reported to occur in as many as 30% of patients (Liebovitch et al., 1992) and to increase with age. They rarely are of enough clinical significance to preclude use (Mulvihill et al., 1983).

Results.

Several papers have reviewed large series of patients after appendicovesicostomy (Cain et al., 1999; Kaefer et al., 1997b; Harris et al., 2000; Thomas et al., 2006; VanderBrink et al., 2011; Welk et al., 2008). Inability to use the appendix, other than because it was needed for use in situ for antegrade continence enemas, has been rare. The results, in terms of continence, have been superb, usually above 95% (Baradaran et al., 2012; Cain et al., 1999;

Castellan et al., 1999; Elshal et al., 2011; Gerharz et al., 1998; Gosalbez et al., 1998; Kaefer and Retik, 1997; Liard et al., 2001; Mor et al., 1997; Suzer et al., 1997; VanderBrink et al., 2011). **Incontinence is a rare event with the Mitrofanoff principle and may result from inadequate length of the flap valve mechanism or persistently elevated reservoir pressure.** Urodynamic evaluation is required to evaluate the cause of the incontinence. Injection of a bulking agent is a possible treatment for inadequate outflow resistance, with success reported up to 50% in the short term (Welk et al., 2008).

A more formal approach with takedown and revision of the leaking Mitrofanoff valve is often required (Kaefer and Retik, 1997). **The most common complication has been stomal stenosis, which in general has occurred in 6% to 10% of patients** (Ardelt et al., 2012; Leslie et al., 2011; Thomas et al., 2006; Welk et al., 2008;). Stenosis resulting in difficult catheterization may occur early in the postoperative course and require formal revision (Harris et al., 2000). Mickelson et al. (2009) have described the successful use of an “L stent” with topical steroid cream as an effective noninvasive treatment. Another recognized complication has been appendiceal perforation. Most problems with stomal stenosis and creation of a false passage (perforation) occur in the first few years after reconstruction, but long-term problems do occur, resulting in the need for lifelong monitoring (Leslie et al., 2011; Thomas et al., 2006). Benign fibroepithelial polyps and inflammatory granulomatous tissue have recently been reported in all types of catheterizable channels. Groth et al. (2013) reported an incidence of polyps occurring in 20% of their patients at a 7-year follow-up; 50% were symptomatic and 45% had a recurrence after resection. Stricture and necrosis, particularly of cecal extensions of the appendix, have occurred rarely. Abdominal stomas may be associated with a higher risk of reservoir calculi because of the potential for incomplete emptying.

Follow-up in the recent series has averaged approximately 4 years. Patients from Mitrofanoff's early experience (1980) now have follow-up of more than 30 years, suggesting that the appendix may provide a durable alternative for pediatric patients, a finding also noted by others (Cain et al., 1999; Harris et al., 2000; Liard et al., 2001). Similar outcomes have been achieved in smaller series of adults (Ardelt et al., 2012; Gowda et al., 2008; Van der Aa et al., 2009).

Alternatives.

When the appendix is unavailable for use, other tubular structures can provide a similar mechanism for catheterization and continence. Mitrofanoff (1980) described a similar technique using a ureter (Kaefer et al., 1997b). Care must be taken to preserve the distal blood supply to prevent ischemia. Refluxing ureters have even been used after extravesical reimplantation (Ashcraft and Dennis, 1986; Duel et al., 1996; Kaefer et al., 1997b). Stomal stenosis seems to be more problematic with use of the ureter compared with the appendix, possibly because of compromised blood supply. In addition, distention of the ureter from catheter passage has caused discomfort in some individuals (Duckett and Lofti, 1993).

Woodhouse and MacNeily (1994) used the fallopian tube, which can accommodate catheterization. Stenosis again appears to be a significant problem with the fallopian tube. The effect on fertility should be considered when there is a normal ipsilateral gonad. Ileum has been tapered to create a similar uniform tube of adequate length (Adams et al., 1992). By narrowing the ileal segment longitudinally along the mesenteric border using permanent staplers in series, the surgeon constructed a surrogate that was easy to catheterize and provided good continence. Others (Hampel et al., 1995; Woodhouse and MacNeily, 1994) have shown similar success with tapered ileum. The catheterizable channel must be long enough to reach from the reservoir to skin without tension but kept as short and straight as possible to facilitate easy catheterization. An unnecessarily long, mobile catheterizable channel can kink and result in difficult catheterization or perforation.

Yang and Monti have been credited with a novel modification of the tapered intestinal segment that can be reimplanted according to the Mitrofanoff principle (Monti et al., 1997; Yang, 1993). A very short (1 to 2 cm) segment of small bowel is opened longitudinally along the antimesenteric border and then closed transversely (Fig. 37.18). By this reconfiguration, the initial circumference of the segment is converted to length and the original length to circumference. A uniform tube is created with a small mesentery toward the center. The two ends are devoid of mesentery, making them easy to tunnel into bladder and bring through the abdominal wall. If the first incision is made directly at the antimesenteric border, both limbs are of equal length. Because the incision is made off of midline and to one side, one limb may be created much longer than the other. Experience has shown that a long tunnel in the bladder or reservoir is not needed to achieve continence with such a small-diameter channel, and the longer limb has typically been used to reach the skin through a thick abdominal wall.

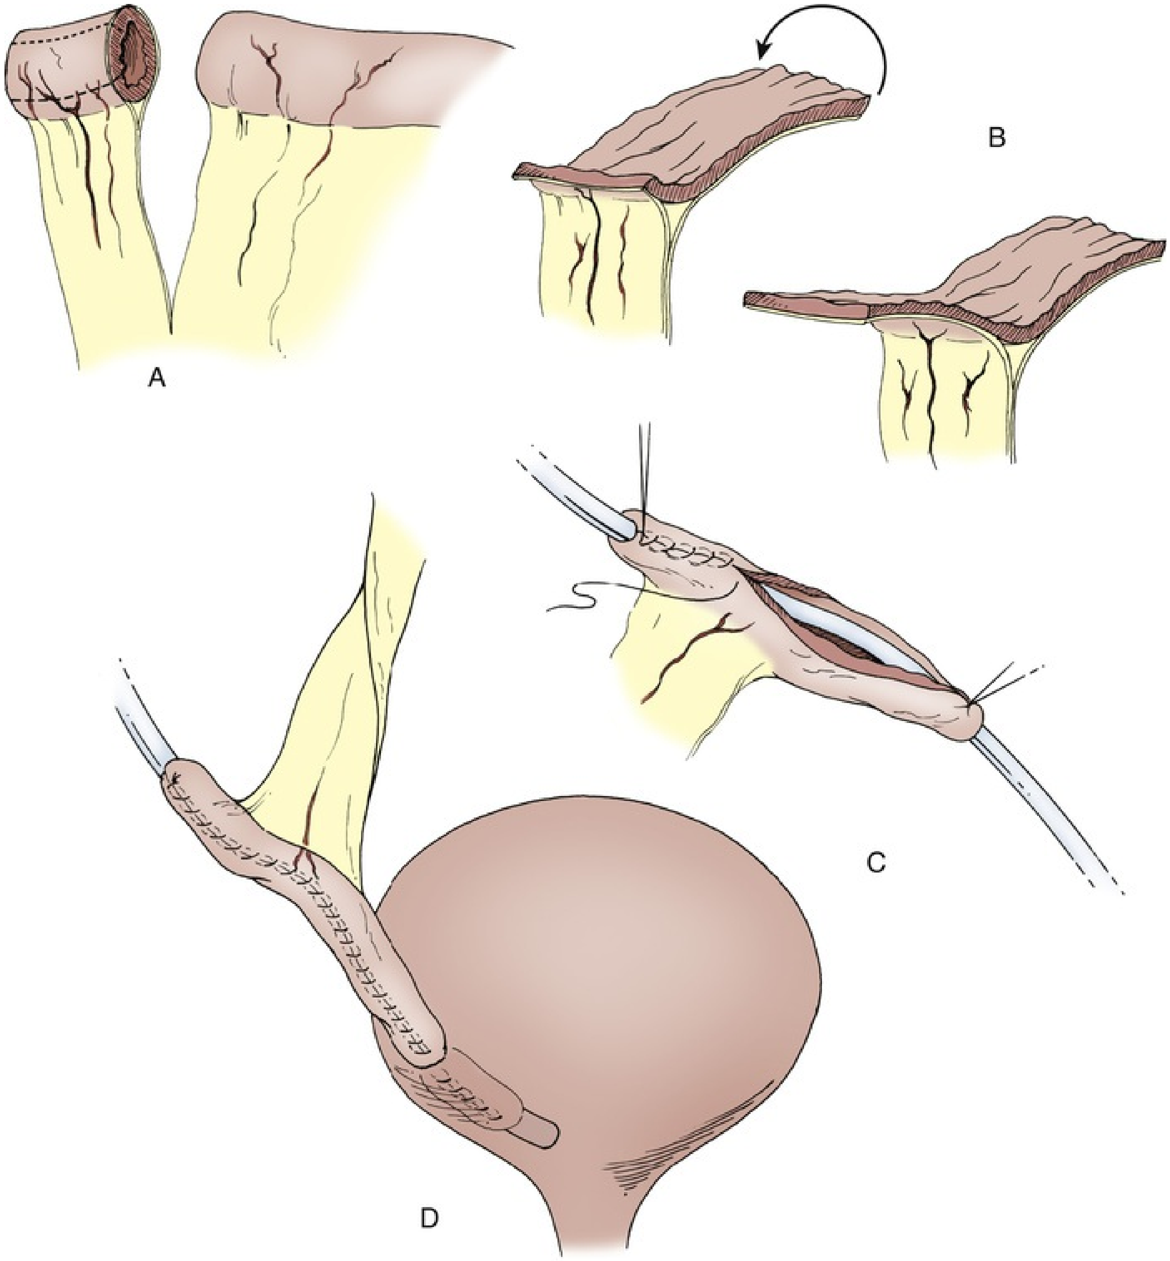

FIG. 37.18 Yang-Monti technique to efficiently construct a catheterizable tube. (A) A 2-cm length of ileum is harvested either independently or next to a segment for augmentation cystoplasty. The segment is opened horizontally and tubularized in a longitudinal fashion. (B) If the segment is opened directly on the antimesenteric border, two equal-length limbs result with a central mesenteric pedicle. Initial incision may be made to one side to form a shorter limb for implantation in the bladder and a longer one to be brought through the abdominal wall. (C) The reconfigured ileal segment is tubularized over a 12-Fr catheter in a two-layer technique with absorbable sutures. (D) A continent catheterizable stoma is constructed.

Very good results have been achieved using the Yang-Monti channel as a catheterizable stoma, and it is certainly an efficient use of bowel (Leslie et al., 2011; Nerli et al., 2013; VanderBrink et al., 2011). Some surgeons have suggested that it may be easier to catheterize than an ileal segment tapered longitudinally because circular mucosal folds are redirected longitudinally in the direction of catheter passage. Stomas created with ileum may have a lower rate of stenosis than those created with appendix (Kaefer et al., 1999b). The one potential disadvantage of the Yang-Monti channel is that it remains relatively short and may not reach the skin without tension in obese patients. Despite extensive use of skin flaps, such tension may lead to stomal stenosis. Two separate reconfigured channels can be anastomosed together for increased length (Kaefer and Retik, 1997). Casale (1999) used an initial segment that was twice as long that was partially split in the middle and then opened in a spiral fashion on opposite sides to create a longer strip that could be tubularized in continuity. A direct comparison of these channel modifications showed similar results in terms of continence, stenosis, and revision rate; however, spiral Monti channels were more likely to need subfascial revision if located at the umbilicus (Whittam et al., 2015). Narayanaswamy et al. (2001) noted difficulty with catheterizations through Yang-Monti channels in 28% of a large series of patients as a result of “pouch-like dilatation.” Such a problem, to that degree, has been avoidable in most series. Excessive length of the extravesical limb may make such dilation more problematic.

Ileocecal Valve

Use of the ileocecal valve as a continence mechanism began with Gilchrist et al. (1950) and was popularized by the Indiana group (Bihrle, 1997; Rowland et al., 1985). Various modifications have been developed. In general, a short segment of terminal ileum, whether imbricated or tailored, is used as an efferent limb. This segment should be kept as short and straight as possible to facilitate easy intermittent catheterization. Continence is based on the imbricated ileocecal valve, not the length of the efferent limb. The imbrication is usually secured with interrupted, permanent sutures, involving the very distal ileum and ileocecal valve, and the imbrication is carried onto the cecum.

The Indiana pouch has been used in children with excellent results as in adults. Besides the appendix, this continence mechanism is perhaps the simplest and has the shortest learning curve to achieve reliable results. Continence rates have been reported as high as 95% with preservation of normal upper tracts (Hensle and Ring, 1991; Kaefer et al., 1997b; Lockhart et al., 1990; Rink and

Bihrle, 1990; Rowland et al., 1985; Rowland, 1995). One report noted a higher rate of incontinence (Canning, 1998). Husmann and Cain (1999) have used the cecal segment for bladder augmentation and the efferent limb to construct a continent catheterizable stoma with good results. They noted a very low incidence of detrimental effect on gastrointestinal function in a select group of patients with neurogenic dysfunction.

Hydraulic Valves

Benchekroun (Benchekroun, 1982; Benchekroun et al., 1989) developed a hydraulic valve as a continence mechanism that was modified by Guzman et al. (1989). Urine from the reservoir and generated pressure is allowed to enter a sleeve of ileum around the catheterizable channel. Compression of the inner tube theoretically provides continence, and early experience was encouraging. Initial continence rates approached 75% and then 90% with a single revision (Benchekroun et al., 1989). Others have been unable to duplicate those results (Leonard et al., 1990b; Sanda et al., 1988). Koff et al. (1989) added a similar hydraulic sleeve around the efferent limb of an Indiana pouch, but the use of such valves has largely been abandoned.

Continent Vesicostomy

Yachia (1997) described creation of a bladder tube fashioned from a wide flap of the anterior bladder wall. An attempt to provide a continence mechanism was fashioned by weaving the bladder tube through the rectus muscle for compression and continence. Continence in their small, short-term series was reported to be 100%, but this has not been duplicated.

Hanna et al. (1999) described a continence mechanism based on either a flap of bladder or intestinal tissue fashioned after prior enterocystoplasty and used it on a very small series of patients. A rectangular flap in continuity with the bladder is tubularized over a 14-Fr to 16-Fr catheter. The bladder is plicated around the proximal 3 cm of the tube using nonabsorbable suture to create a type of nipple similar to gastric fundoplication. Macedo and Srougi (2000) described a similar continence mechanism created at the time of initial augmentation. They achieved acceptable continence in eight of their first nine patients. Their technique is potentially appealing for patients requiring augmentation and having no appendix because of the simplicity; however, continence is based on a type of nipple valve that historically has been difficult to keep fixed. The same forces that create continence tend to efface the continence mechanism.

Casale (1991) has described a form of continent vesicostomy in which the continence mechanism is based on a flap valve created from a tubularized strip of bladder mucosa. It is particularly suitable when the bladder is compliant and of large capacity. An anterior detrusor strip is used to create a catheterizable limb.

Technique.

Parallel incisions 3 cm apart are made into the anterior bladder and used to create a long rectangular flap. The abdominal wall should be measured to ensure that the strip is long enough to reach the skin without tension. The full-thickness strip is tubularized down to the bladder in two layers. The muscle portion is left broad to come around without tension and provide good blood supply. The mucosa may be trimmed in width before tubularization to avoid redundancy. A strip of mucosa within the bladder, 2 to 3 cm in length and 1.5 cm in width, is incised in a direct line and in continuity with the mobilized bladder tube. The edges of this strip are mobilized until it can be tubularized along its entire length. It may be beneficial to mobilize only one edge over to the other side to avoid overlapping suture lines. Casale (1991) originally incised the mucosa transversely at the end of the intravesical strip to be tubularized; Rink et al. (1995b) then suggested that it could be left intact (Fig. 37.19). The bladder mucosa from either side of the channel is then mobilized and closed over the mucosal tube to create a flap valve. More extensive mobilization of the side opposite that mobilized for the inner tube allows closure without overlapping suture lines, which may help avoid fistula formation and incontinence. A stent is left in the channel for 3 weeks to prevent stenosis. It does tend to stricture if not catheterized regularly—more so than other catheterizable channels (Cain et al., 2002; Thomas et al., 2005).

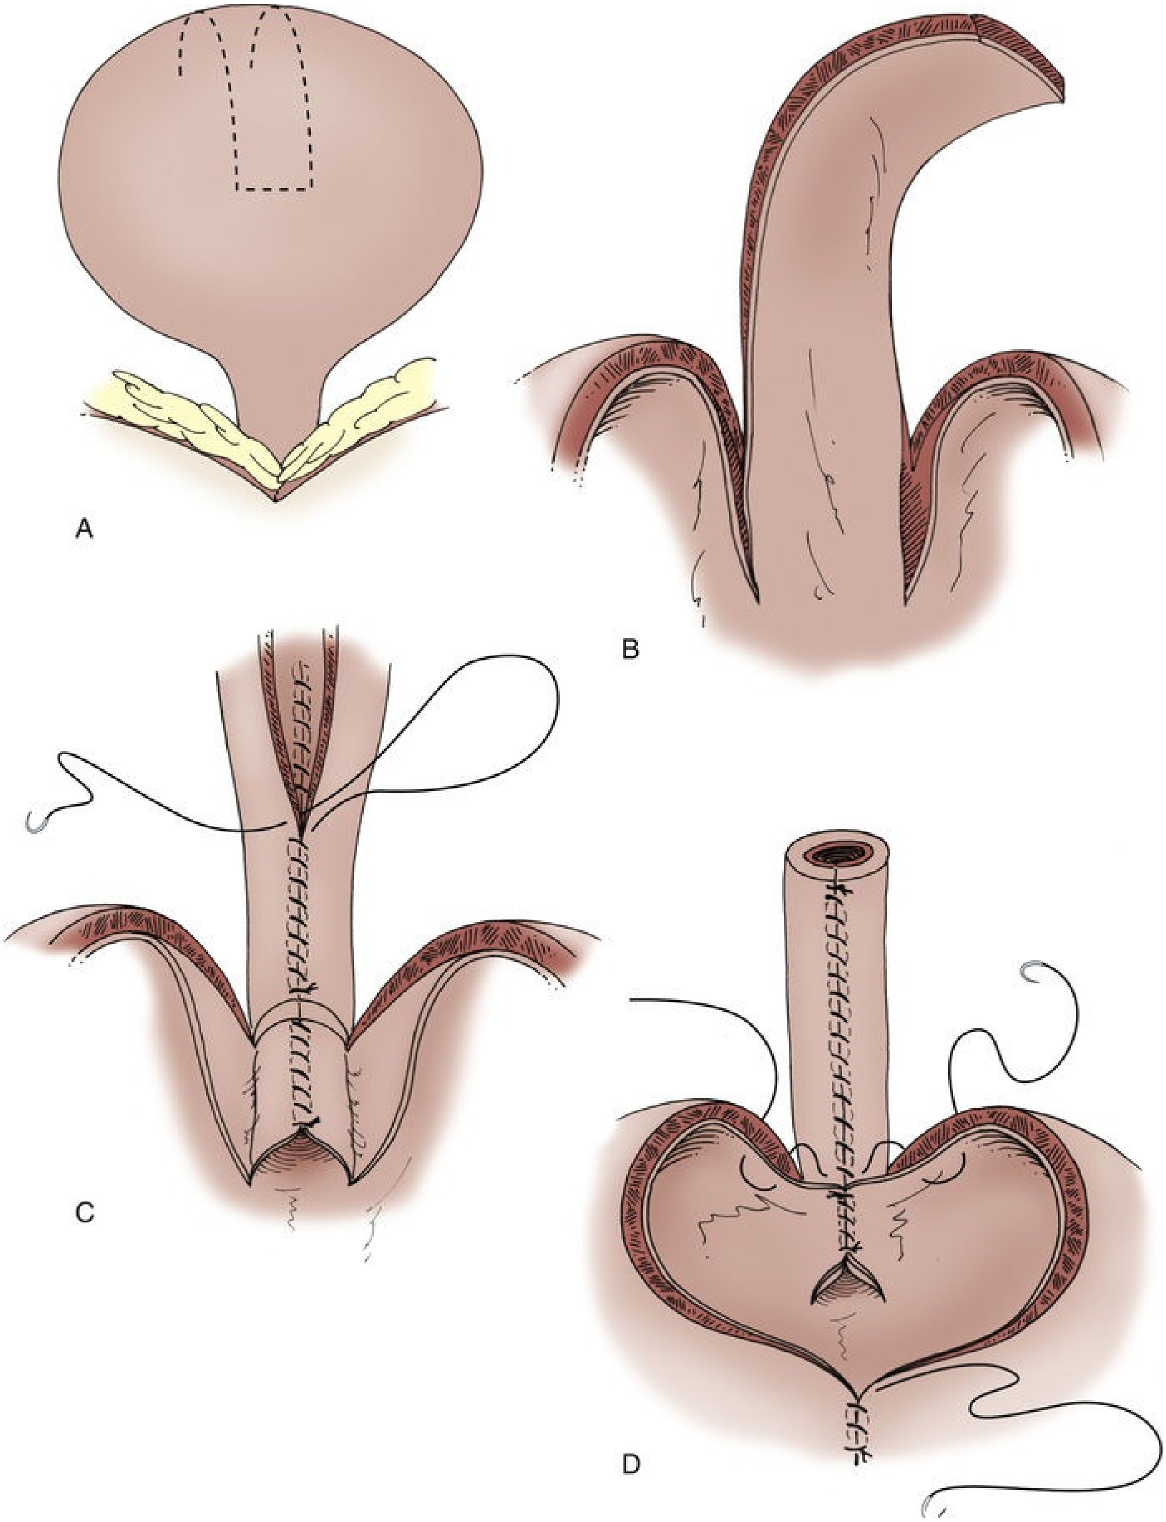

FIG. 37.19 Casale continent catheterizable stoma. (A) Parallel incisions are made in the bladder dome, forming a full-thickness bladder strip. (B) The epithelium of the bladder is then incised for an additional 2.5 cm. The edges of the epithelium are mobilized, allowing tubularization. (C) The

epithelium is tubularized from the bladder out to the tip of the strip with an absorbable suture. The muscle of the bladder strip is then tubularized with an absorbable suture. (D) The lateral edges of the epithelium within the bladder are reapproximated over the tubularized bladder segment with absorbable suture. The bladder is then closed with absorbable suture, incorporating the bladder tube with the initial sutures to prevent kinking.

Results.

Continence rates have been good, as with most flap valves (Cain et al., 1999, 2002). Stomal stenosis remains a significant problem for 45% in the experience at Indiana University (Cain et al., 2002). Skin flaps and avoidance of tension to reach the skin may minimize this risk but do not eliminate it. Advantages include avoidance of an intraperitoneal procedure and bowel anastomosis; the appendix can be reserved for use with enemas. It does use some bladder and decrease capacity, which may not be appropriate for many patients.

Results With Pediatric Continent Diversion

The most challenging aspect of continent diversion in children remains construction of an efferent limb that provides reliable continence and easy catheterization (Ardelt et al., 2012). The continence mechanism most familiar to pediatric urologists is the flap valve. The appendix is simple to use, suitable for most children, and associated with very good continence rates. If the appendix is not present or is to be used for antegrade colonic enemas, tapered intestinal segments provide a nice alternative. Nipple valves are the most complex continence mechanism and therefore have a longer learning curve. Continence rates approaching 85% can be expected with stapled nipple valves (Benson and Olsson, 1998; Kaefer et al., 1997b) after extensive experience. With use of the other efferent limbs, continence rates above 90% and approaching 95% have been reported in children (Ardelt et al, 2012; Duckett and Snyder, 1986; Hensle and Ring, 1991; Kaefer et al., 1997b; Surer et al., 2003).

Children undergoing continent diversion have a long life expectancy. With proper patient selection and appropriately performed continent diversion, postoperative hydronephrosis in children is rare and is not increased when compared with conduit diversion (Stein et al., 2000). In cases of catheterization not being performed reliably, however, new hydronephrosis was reported (Abd-El-Gawad et al., 1999). The incidence of complications after continent diversion will undoubtedly increase with longer follow-up. These patients will be subject to the same complications seen with bladder augmentation. All of those complications, including infection, hydronephrosis, calculi, spontaneous perforation, and tumor, have been reported after continent diversion in adults if not in children. These are largely a function of the use of intestine as a urinary reservoir. Because more intestine is usually required in continent diversion than bladder augmentation, the incidence of complications may ultimately be higher than with simple augmentation. Already, serum changes of increased chloride, decreased bicarbonate, and acidosis have been noted in some patients after continent diversion (Allen et al., 1985; Ashken, 1987; Boyd et al., 1989; McDougal, 1992a; Thuroff et al., 1987). Spontaneous perforation has occurred in up to 1.5% of patients (Mansson et al., 1997).

The most common complication in pediatric continent diversion thus far has been stomal stenosis. Stenosis occurs more commonly at the umbilicus with use of appendix compared with tapered ileal segments (Fichtner et al., 1997; Kaefer et al., 1999b). Various skin flaps may be placed into the terminal end of the appendix or intestinal segment to lower the rate of stenosis, but they do not eliminate stenosis (Kajbafzadeh et al., 1995; Landau et al., 2008). Ardelt et al., after extensive review (2012), found no consensus that a single type of efferent limb is superior and suggested that the choice of technique should be individualized according to the case.

Key Points: Continent Urinary Diversion

- "Pure" continent diversions have been used in children with good results similar to those expected in adults.
- Flap valves provide a reliable continence mechanism with appendix or reconfigured intestinal segments.
- The efferent limb should always be kept as short and straight as possible to facilitate catheterization.

Stomal stenosis is the most common complication of pediatric continent diversion.

Other Considerations

Use of Buttons as Alternative Means to Empty Bladder

The Mic-Key button (Ballard Medical Products, Avanos Medical, Alpharetta, GA) and Mini balloon button (Applied Medical Technology, Brecksville, OH) can be used as an alternative means to empty the bladder in patients with neurogenic bladders. The ideal patient is one who is not a candidate for augmentation and/or CIC. A variety of sizes are available. This technique only allows for bladder drainage, either intermittent or continuous, depending on whether the drainage adaptor is in place (Lopes and Lorenzo, 2016).

Technique.

Although these buttons can be placed percutaneously under cystoscopic guidance as a primary approach, we have found it helpful to initially place a suprapubic tube to allow for an established tract. The button can then be placed with or without a guidewire in the outpatient setting. The appropriate size can be chosen with the included sizing tool, and one can change the length of the button over time depending on the patient's body habitus.

Transitional Care Considerations

As children with spina bifida and other similar conditions age, the need for adult care of pediatric urologic problems has grown in concert. This patient care need has led to the emergence of a new field of urologist, the transitional urologist, the detail of which will be covered in greater degree elsewhere in this book. However, when considering transitional care associated with patients who have undergone lower urinary tract reconstruction, certain factors must be considered. Such factors include the mortality that can arise from medical noncompliance. Several important studies from Husmann highlight the role of the transitional urologist in patients who have been reconstructed. One study from Husmann (2017) draws attention to the various causes of morbidity and mortality in a contemporary population of patients after lower urinary tract reconstruction. In this report of 385 patients with a history of bladder augmentation, significant long-term complications include spontaneous bladder rupture in 3% of patients with rupture leading to death in 1 patient. Factors that contributed to bladder rupture include substance abuse, mental/physical deficits, and noncompliance with catheterization. In another report by Husmann from 2016, the author further highlights the scrutiny needed in transition patients who have been augmented. Reporting on the same population of patients as the 2017 article, the study finds that 240 mL of saline bladder irrigation daily was highly effective in reducing bladder calculi in the post-augmented patient. Furthermore, the article draws attention to a population of 80 patients undergoing bladder augmentation and concomitant bladder neck procedures. At 14 years of follow-up, 40% of these patients developed new renal scars, and 32% of those patients went on to develop stage 3 chronic renal disease or higher. Yet again, compliance with catheterization was a driving factor in the development of upper tract deterioration, further underscoring the need for routine follow-up of patients in late adolescence and adulthood. Another concern in the augmented patient is the development of bladder cancer and the possible effect that augmentation has on this risk. Several studies show that the overall risk for bladder cancer in spina bifida patients is approximately 2% to 4% (Husmann, 2017; Rove et al., 2017). A recent systematic review examined 28 studies, most of which were case reports, totaling 52 spina bifida patients with a bladder cancer diagnosis. Notably, 71% of these patients had aggressive disease with stage III or stage IV cancer at the time they were diagnosed. Yet, the presence of a bladder augmentation with segments other than stomach did not appear to increase the risk for developing bladder cancer. The authors encourage physicians to counsel their patients on the risk of developing cancer given the aggressive disease at the time of presentation (Rove et al., 2017). In conclusion, it is clear that pediatric patients undergoing bladder augmentation remain at lifelong risk for complications and that a well-trained adult urology provider must play a role in their care. Providers caring for adult patients must keenly assess for compliance with catheterization, maintenance of a daily bladder irrigation program, and signs of upper tract deterioration, particularly in those who have had augmentation with bladder outlet procedures.

Summary

Every effort should be made to treat pediatric bladder dysfunction, no matter what the cause, early and aggressively to minimize the number of patients requiring reconstructive surgery for bladder and sphincter dysfunction. Some such surgery will still be necessary, and the patients must be carefully evaluated so that all problems are identified and addressed. The surgeon should then be flexible and prepared to use the bowel segments and techniques that best fit each patient. **Although a given surgeon's results using any technique may improve with experience and confidence, each patient's unique problems and anatomy may make some choices better than others. Forcing one procedure to fit every patient should be avoided.**

Preoperative evaluation should identify upper tract obstruction or vesicoureteral reflux. Such problems should be corrected at the time of surgery, although low-grade secondary reflux usually resolves spontaneously with correction of bladder dysfunction. It is imperative to provide the patient with an adequate bladder or reservoir, one capable of holding at low pressure a urinary volume that will be produced between voidings or catheterizations. This can be accomplished by either augmentation or construction of a continent reservoir using any gastrointestinal segment. Each has its own set of advantages and disadvantages that should be considered. If adequate outflow resistance is lacking, it should be created at the bladder neck to prevent incontinence. Any patient undergoing reconstructive surgery for bladder or sphincter dysfunction must be prepared and capable of performing intermittent catheterization on a reliable basis; most will require it routinely. This is particularly true of those patients with neurogenic dysfunction.

As much of the patient's native urinary tract as possible should be preserved in pediatric urologic reconstruction. The urothelial lining avoids much of the morbidity associated with intestinal segments. If necessary, however, virtually any portion of the lower urinary tract may be reconstructed or replaced using intestine. Unfortunately, occasional complications do occur when intestinal segments are used in that manner. They are not perfect physiologic substitutes. Patients after reconstruction require a lifetime of follow-up, and that observation should include careful evaluation of their true quality of life. The most important factor in avoiding problems with such complex pediatric patients is the motivation of the patient and family to achieve a successful outcome.

Assessment of that commitment is critical.

Anomalies of the Upper Urinary Tract

Brian A. VanderBrink MD, Pramod P. Reddy MD

Anomalies of Renal Number

Renal function is crucial for sustaining life, and therefore nature provided us with an adequate renal reserve (typically two functioning kidneys) to protect against kidney disease or damage. In this section of the chapter, we will focus on congenital absence of one or both kidneys and the rare instance of supernumerary kidneys. *Agenesis* implies the congenital absence of an organ resulting from failure to develop during embryonic growth and development because of the absence of primordial tissue. Strictly speaking, individuals who have a congenital solitary kidney caused by early involution of a multicystic displastic kidney (MCDK) do not have renal agenesis.

Bilateral Renal Agenesis

Of all the congenital anomalies of the upper urinary tract, bilateral renal agenesis (BRA) has the most profound effect on the fetus, and it is almost always incompatible with life. Although Wolfstrigel first recognized BRA in 1671, it was not until Potter's extensive description of the constellation of associated defects that the full extent of the syndrome could be easily recognized (Potter, 1946a, 1946b, 1952, 1965). Because of the myriad of complex molecular events that are required for normal renal development, there is probably no single underlying etiology for BRA.

Incidence

The incidence of BRA is exceedingly rare, with only about 500 cases reported in the literature (Potter, 1965). It is estimated that BRA occurs once in 4800 to 5000 births, whereas Stroup et al. detected an incidence of 3.5 per 100,000 (Stroup et al., 1990). A study in 8500 pregnancies in Poland documented a higher incidence of 0.25% (Forys et al., 2003). Almost 75% of affected individuals are males. Increasing maternal age may be a risk factor (Bianca et al., 2003), but complications of pregnancy or maternal disease such as diabetes mellitus do not appear to influence the incidence of BRA (Ruhland et al., 1998). An autosomal recessive inheritance pattern may exist (Dicker et al., 1984), although other investigators have suggested an autosomal dominant trait with variable penetrance (Kovacs et al., 1991; Murugasu et al., 1991; Moerman et al., 1994). When siblings and parents of an index child with BRA were screened, 4.5% had unilateral renal agenesis (URA) (Roodhooft et al., 1984) and 3.5% had BRA (McPherson et al., 1987). This is 1000 times higher than in the general population (Stroup et al., 1990). McPherson et al. evaluated renal anomalies in families of individuals with congenital solitary kidneys including renal agenesis or a very poorly functioning kidney resulting from dysplasia/hypoplasia (McPherson, 2007). The empirical risk of 7% for offspring, 4% for parents, and 2.5% for siblings may be an underestimation, because not all relatives underwent ultrasound screening. The incidence of BRA in offspring of congenital solitary kidney probands was approximately 1%, which is significantly greater than the risk found in the general population but less than that for families with a history of BRA. Ultrasound screening has been recommended for parents and siblings of infants born with either URA or BRA or renal dysgenesis (Roodhooft et al., 1984). McPherson reviewed families in whom a first-degree relative had been diagnosed with a solitary kidney and noted a significant incidence of renal anomalies; based on this, he has recommended prenatal and/or postnatal ultrasound examination when either parent or another first-degree relative has a congenital solitary kidney (McPherson, 2007).

Syndromic associations with BRA have been detected in higher than expected proportions in cases with esophageal atresia (Saing et al., 1998), cryptophthalmos, Fraser syndrome (syndactyly, renal abnormalities, genital malformations, and cryptophthalmos) (Fryns et al., 1997), Klinefelter syndrome (Barroeta and Stopyra, 2004), and Kallmann syndrome (Colquhoun-Kerr et al., 1999).

Relevant Renal Embryology and Possible Etiology

The embryologic development of the renal system is closely integrated with the developing genital system, hence abnormalities with renal development are associated with malformations of the genital system in both genders. **The intermediate kidney, or mesonephros, develops and then regresses, leaving behind the mesonephric tubules** (Uetani and Bouchard, 2009; Costantini and Kopan, 2010). In the male, these are the efferent ductules that serve as a link between the gonad and the mesonephric duct or Wolffian duct (WD) structures (the body and tail of the epididymis and vas deferens). In the female, the mesonephric tubules link the ovary through the fimbriated end of the fallopian tube to the reproductive tract. **The definitive kidney differentiates from the**

metanephric blastema, which is a specialized region of the intermediate mesoderm termed the *metanephric mesenchyme (MM)*. This process requires the reciprocal induction between the metanephric blastema and the ureteral bud (UB), which is critical for the kidney to form. The metanephric blastema sends signals to the WD to initiate UB formation from its caudal end between 5 and 7 weeks' gestation. The UB evaginates and invades the metanephric blastema and branches repeatedly in a characteristic pattern to form the renal collecting duct system. The ureteral tips induce nephron differentiation in the adjacent mesenchyme, forming the mature metanephros (Uetani and Bouchard, 2009). The absence of a nephrogenic ridge on the dorsolateral aspect of the coelomic cavity, or the failure of a UB to develop from the WD, will result in ipsilateral renal agenesis. Therefore, for BRA to occur, there must be an alteration in normal molecular development or a mutation that causes renal or ureteral maldevelopment on both sides of the midline.

Mammalian Kidney Organogenesis: New Advances in Developmental Biology

Renal agenesis is the result of a failure of the UB to develop from the mesonephric duct (WD) or a failure of the reciprocal induction of the UB and the metanephric blastema. Mutations in *RET* (Rearranged in Transfection) were found in 7 of 19 fetuses with BRA and in 2 of 10 fetuses with URA. A mutation in *GDNF* was found in 1 fetus with URA who also had mutations in *RET*. No *GFRα1* mutations were observed. These data suggest that congenital renal agenesis results from *RET* mutations that prevent or impede the embryonic development of *RET*-dependent structures. After the GDNF/GFRα1 complex binds to RET, the *Wnt11* gene is activated in the epithelial tips of the UB and is associated with UB branching (Majumdar et al., 2003).

Gremlin 1 (GREM1) is an extracellular BMP antagonist that is expressed in the mesonephric mesenchyme and in the MM (Michos et al., 2004). GREM1 is upregulated in the mesenchyme around the origin of the UB before the initiation of its outgrowth. At this time, BMP activity is reduced locally. **In the *Grem1*-deficient mouse embryo, metanephric development is disrupted at the stage of UB outgrowth initiation, resulting in BRA. This inhibition of UB outgrowth causes progressive loss of *Gdnf* expression, resulting in apoptosis of the MM.** To examine further the relationship of these various ligands and their effects on epithelial-mesenchymal interactions, Michos et al. cultured early *Grem1*-deficient mutant mouse kidney rudiments in a medium supplemented with recombinant GREM1 (Michos et al., 2007). The addition of GREM1 restored UB outgrowth and induced supernumerary epithelial buds that invaded the MM and initiated branching morphogenesis. At the molecular level, GREM1 replacement activated *Wnt11* expression in the epithelial buds and upregulated *Gdnf* expression in the mesenchyme. Because genetic suppression of BMP4 activity in a *Grem1*-deficient mouse model completely restored kidney development, *the local reduction of BMP4 activity by GREM1 was presumed to be critical to the initiation of UB outgrowth and kidney organogenesis*. Because BMP4 signaling by the mesenchyme surrounding the WD prevents the formation of supernumerary epithelial buds, successful initiation of UB outgrowth most likely requires both the antagonism of BMP4 by GREM1 in mesenchyme and the signaling by GDNF from the MM to RET in the ureteric epithelium (Michos et al., 2007). In addition, autoregulatory feedback signaling between GDNF in the mesenchyme and WNT11 in the epithelial tips regulates branching morphogenesis. *Grem1* is essential for both upregulation of *Wnt11* in the ureteric epithelium and *Gdnf* expression in the mesenchyme and the establishment of epithelial-mesenchymal feedback signaling. The renin-angiotensin system (RAS) has also been shown to be essential to normal renal development (Yosypiv, 2014). Gene mutations of the RAS lead to a spectrum of congenital anomalies of the kidney and urinary tract (CAKUT) resulting from defects in UB morphogenesis. UB tips induce surrounding mesenchymal cells to undergo mesenchymal to epithelial transition, forming the glomerulus to the distal tubule. Therefore, a decrease in UB branching efficiency will result in a significant decrease in nephron endowment. Aberrant branching can result in abnormal nephrogenesis and renal dysplasia. In the RAS, renin cleaves angiotensinogen to angiotensin I, which is converted to angiotensin II by the angiotensin-converting enzyme (ACE) (Yosypiv, 2014). Angiotensin II, the primary effector peptide growth factor of the RAS, acts through two major protein receptors: AT1R and AT2R. Angiotensin II acts through the AT2R to stimulate UB branching by upregulating PAX2, a downstream regulator of GDNF that induces the expression of *GDNF/Ret/Wnt11* pathway genes. These genes promote proliferation in UB tip cells and stimulate UB branching. The critical role for the RAS in UB morphogenesis is observed when ACE inhibitors or AT1R antagonists are administered during pregnancy. These inhibitors cause abnormal nephrogenesis, more specifically, renal tubular dysgenesis, which is characterized by absent or underdeveloped proximal tubules. In mice, gene inactivation of angiotensinogen, renin, ACE, or AT1R results in renal pelvic dilation and hypoplastic papilla. Mutations in the *AT2R* gene in mice result in downregulation of the *GNFR/Ret/Wnt11* pathway gene expression, decreased proliferation, and induction of apoptosis of the UB cells. **Clinically, ureteral duplication and vesicoureteral reflux are associated with *AT2R* gene mutations.** These observations in receptor-deficient mice illustrate the need for a critical balance of cell proliferation and cell apoptosis in normal UB branching and nephrogenesis. *SOX* genes are an essential component of the c-RET signaling pathway and are important developmental regulators expressed in the tips of the UB that are thought to direct UB branching.

Gross Pathologic Description of Retroperitoneal Findings in Bilateral Renal Agenesis

In an extensive autopsy analysis by Ashley and Mostofi, the kidneys were completely absent on gross inspection of the entire retroperitoneum (Ashley and Mostofi, 1960). Complete absence of the renal vessels was observed in about 25% of specimens. **Complete ureteral atresia was observed in 39 of the 42 cases of BRA, and partial ureteral absence was noted in three cases.** With complete absence of the ureter, a rudimentary kidney was discovered in only a few instances.

The adrenal gland may appear flattened (“lying down” sign) on ultrasonography and is usually orthotopic in location; only rarely is the adrenal gland malpositioned or absent (Hoffman et al., 1992) **(Fig. 38.1).** A normally located adrenal gland is expected, because the adrenal cortex embryologically develops independent from the kidney, arising from primitive mesoderm, medial to the urogenital ridge. The medulla develops from ectodermal neural crest cells, whereas the metanephros is derived from the intermediate mesoderm (MM). Fused and/or horseshoe-shaped adrenal glands have been noted on prenatal ultrasound screening (Strouse et al., 2002). Potter noted that fused adrenal glands were often found in the presence of spinal anomalies (Potter, 1965). In a small number of autopsies, the gonads were absent, indicating that the insult occurred before the fifth week and affected the development of the urogenital ridge (Carpentier and Potter, 1959). In the Ashley and Mostofi series, about 50% of cases of complete ureteral atresia showed complete absence of the bladder, and in the remainder, a hypoplastic bladder was found consisting only of a muscular tube with a minuscule lumen (Ashley and Mostofi, 1960). In Potter's series, the bladders were also hypoplastic and lacked ureteral orifices. A normally closed urachus was observed. Abnormal development of the bladder is thought to be the result of a lack of stimulation by fetal urine production, which starts at 10 to 12 weeks' gestation. Alternatively, it has been postulated that UB and WD structures migrating into the ventral cloacal region are needed to initiate normal bladder development. The absence of the UB, and not the *lack* of urine, may arrest bladder development (Katz and Chatten, 1974). This theory is supported by the fact that, despite the absence of bladder filling in bladder exstrophy, many of these bladders are functional following surgical closure alone, whereas the bladders associated with bilateral ureteral ectopia (below the bladder neck) almost invariably require augmentation (Jayanthi et al., 1997; Gearhart and Mathews, 2007).

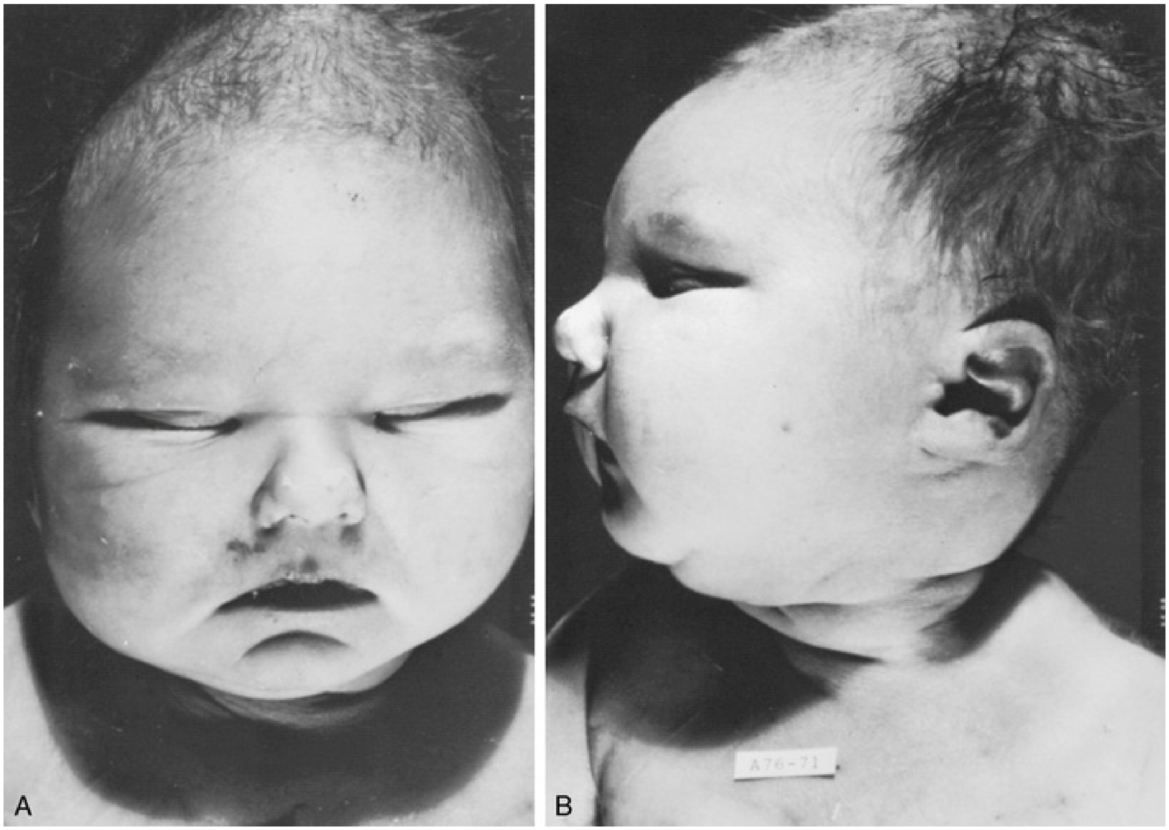

FIG. 38.1 An anephric child who lived 2 days has the typical Potter facial appearance. (A) Note the prominent fold and skin crease beneath each eye, blunted nose, and depression between the lower lip and chin. (B) The ears give an impression of being low set because lobes are broad and drawn forward, but actually the ear canals are located normally.

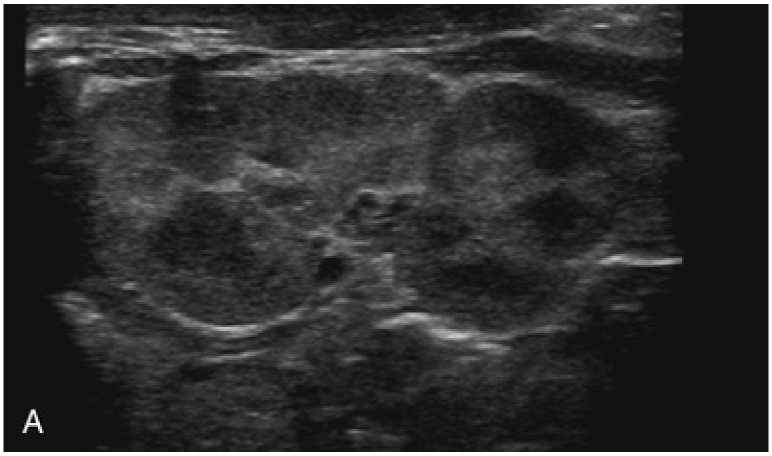
Phenotypic Features Associated With Bilateral Renal

Agenesis

Potter has extensively described phenotypic features associated with BRA. These infants have low birth weights, ranging from 1000 to 2500 g, and intrauterine growth restriction (IUGR) resulting in part from low iron stores in the liver (Georgieff et al., 1996). **The characteristic facial appearance and deformity of the extremities distinguishes these neonates from healthy newborns (Fig. 38.2).** The infants look prematurely senile and have “a prominent fold of skin that begins over each eye, swings down in a semicircle over the inner canthus and extends onto the cheek” (Potter 1946a, 1946b). This facial feature is a sine qua non of the absence of amniotic fluid, resulting from the lack of functioning renal parenchyma. The nose is blunted, and a prominent depression exists between the lower lip and chin. The ears appear to be low set, are drawn forward, and are often pressed against the side of the head, making the lobes seem unusually broad and exceedingly large. Periauricular pits and tags have been noted (Wang et al., 2001). The skin can be excessively dry and appears too loose for the body. The hands are relatively large and clawlike. The legs are often bowed and clubbed, with excessive flexion at the hip and knee joints (Das et al., 2002). Occasionally the lower extremities are completely fused as seen with sirenomelia (Liatsikos et al., 1999). A lumbar meningocele with or without the Arnold-Chiari malformation and hydrocephalus has been observed (Ashley and Mostofi, 1960). In Potter's series, anomalies of the gastrointestinal tract were found in 60% of fetuses. Anomalies of the external genitalia are commonly encountered (Potter, 1965).



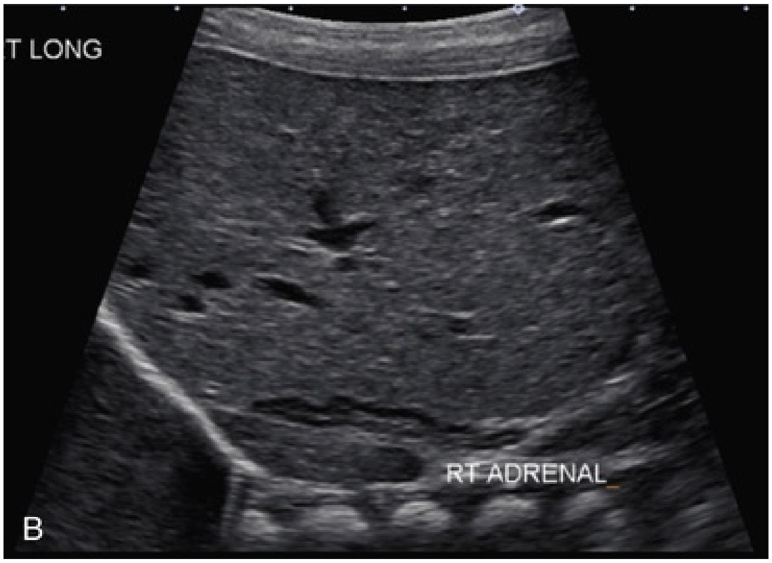


FIG. 38.2 Two-month-old infant with prenatally detected solitary kidney. (A) Postnatal sonogram showing left kidney. (B) Postnatal sonogram showing empty right renal fossa with the "lying down" adrenal sign, a feature seen with renal agenesis or renal ectopia in which the adrenal gland on the affected side appears flattened, elongated, and lying along the spine because of absence of the ipsilateral kidney.

Genital abnormalities in a male fetus with BRA include absence of the scrotum. Penile development is usually normal, but in a few cases, penile agenesis or a rudimentary penis and scrotum has been reported (Potter, 1965; O'Connor et al., 1993). Hypospadias is rare and does not appear to be related to the presence or absence of the testes. **The testes are undescended in 43% of cases** (Carpentier and Potter, 1959). Ashley and Mostofi found testicular agenesis in 10% of cases (Ashley and Mostofi, 1960). The vas deferens is normal in most cases, implying that the factor responsible for the renal agenesis influenced the UB *only after* it formed from a completely elongated WD or that the insult affected the induction of the MM.

Genital abnormalities in a female fetus with BRA include clitoral hypertrophy, which has been noted in a number of cases. There is a relatively high incidence of anomalies of the MD structures and ovaries (Carpentier and Potter, 1959). The ovaries are frequently hypoplastic or absent. The uterus is usually rudimentary or bicornuate but occasionally absent. The vagina is a short, blind-ending pouch or is completely absent.

Role of Amniotic Fluid Production in Fetal Pulmonary Development

The characteristic facial and limb features may result from deformations rather than malformations of structures as a result of the lack of "cushioning" from amniotic fluid (Thomas and Smith, 1974). This observation was confirmed by an experiment in nature, involving a case of mono-amniotic twins, in which one twin with BRA did not have the characteristic Potter facies because it shared the same amniotic sac with the second twin, who had an adequate volume of amniotic fluid (Klinger et al., 1997). Fetal urine is the major source of amniotic fluid, accounting for more than 90% of its volume by the third trimester (Chevalier and Roth, 2007). Pulmonary hypoplasia and a bell-shaped chest are commonly associated findings that were thought to be caused by uterine wall compression of the thoracic cage as a result of oligohydramnios (Bain and Scott, 1960). Fetal lung development begins in the fifth week of gestation with the pseudo-glandular phase and involves branching to form the terminal bronchioles. The critical phase of fetal lung development that is dependent on the presence of amniotic fluid is between 16 and 26 weeks' gestation, which is called the *canalicular phase*. During this phase, terminal bronchioles divide into two or more respiratory bronchioles, which in turn divide into three to six alveolar ducts. Pulmonary airway branching occurs between 12 and 26 weeks' gestation (Reid, 1977; Marszalek et al., 1999; Copland and Post, 2004; Keller et al., 2004). A reduction in the number of branches and a decrease in acini formation in fetuses with BRA imply interference with this process before 16 weeks' gestation (Hislop et al., 1979). It has been suggested that the anephric fetus fails to produce proline, which is a prerequisite for collagen formation in the bronchiolar tree. The fetal kidneys are a primary source of proline, which along with ornithine is required for synthesis of polyamines that are key regulators of gene expression, protein synthesis, and angiogenesis (Clemmons, 1977; Wu et al., 2013). Thus, pulmonary hypoplasia in fetuses with renal abnormalities was thought to mainly result from the absence of renal parenchyma and not from diminished amniotic fluid. This hypothesis is supported by the finding of normal lungs in two infants with prolonged leakage of amniotic fluid beginning at a time when pulmonary hypoplasia would have been expected if the amniotic fluid alone was responsible for the defect (Perlman et al., 1976; Cilento et al., 1994). Peters et al. proposed a two-step process in pulmonary development, with a primary "renal growth factor" influencing early lung development and an amniotic fluid volume–dependent phase influencing later gestational lung growth (Peters et al., 1991a). Smith et al. studied early lung development using a murine knockout model of renal agenesis/dysgenesis and anuria (Smith et al., 2006). They found that pulmonary development occurred early in embryogenesis and showed that hypoplastic lung development preceded the onset of oligohydramnios. These observations support the two-step model proposed by Peters (Peters et al., 1991a). This model is further supported by the fact that oligohydramnios resulting from experimentally induced urinary obstruction is associated with pulmonary hypoplasia in fetal sheep that initially showed normal renal function (Peters et al., 1991a). Restoring amniotic fluid volume only partially restores lung growth. Therefore, uropathy-associated pulmonary hypoplasia appears to be a predominantly the result of oligohydramnios during the canalicular phase of lung development rather than renal dysfunction (Peters et al., 1991b). This observation is further supported by the fact that in some cases of anhydramnios or severe oligohydramnios, serial transabdominal amnioinfusion with saline has improved the fetal lung volume and also postnatal neonatal lung function (Vergani et al., 1997; Szabo et al., 2001).

Prenatal and Postnatal Diagnosis of Bilateral Renal Agenesis

BRA is usually diagnosed by prenatal ultrasonography in the second or third trimester, when severe oligohydramnios is noted and no renal parenchyma can be identified (Forys et al., 2003). Additional diagnostic findings include small lung volumes and chest diameter and abnormal adrenal gland appearance (Heling et al., 2001; Strouse et al., 2002). **The characteristic Potter facies and the presence of oligohydramnios are pathognomonic.** Amnion nodosum—small, white, keratinized nodules on the surface of the amniotic sac—has been considered a placental hallmark of severe oligohydramnios, but the condition is not pathognomonic, and the finding should be interpreted with caution (Adeniran and Stanek, 2007). In a study of 500 infants, every infant voided within the first 24 hours of life, regardless of gestational age (Clark, 1977). After the first 24 hours, anuria without any distention of the bladder is strongly suggestive of BRA.

Postnatal Radiographic Evaluation of a Neonate With Bilateral Renal Agenesis

Renal ultrasonography is the most efficient way to identify and assess the morphology of the kidneys and bladder and to confirm the presence or

absence of urine production. Power Doppler ultrasonography has been highly accurate in determining the status of the renal arteries and documenting blood flow, even in fetuses with suspected BRA (Sepulveda et al., 1998). A flattened orthotopic adrenal gland supports the diagnosis of an absent ipsilateral kidney (Hoffman et al., 1992) (see Fig. 38.1). If abdominal ultrasonography is inconclusive about the presence or absence of kidneys, a radionuclide scan with 99mTc-dimercaptosuccinic acid (^{99m}Tc-DMSA) can be performed at any time after birth. The absence of uptake of the radionuclide in both renal fossae above background activity and in an ectopic location confirms the diagnosis of BRA.

Prognosis for the Patient With Bilateral Renal Agenesis

About 40% of the affected fetuses are stillborn. Of those neonates born alive, most do not survive beyond the first 24 to 48 hours because of respiratory distress and the inability to provide adequate ventilatory support to the profoundly hypoplastic lungs. However, there have been rare instances in the past few years following prenatal interventions for fetuses with BRA permitting the delivery of a "pulmonary survivor," (i.e., fetus with functioning lung tissue and end-stage renal disease [ESRD]) (Sherer et al., 1992; Cameron et al., 1994). These isolated cases of successful deliveries of live neonates with BRA has prompted the ethical dialogue of whether such interventions are appropriate (Sugarman et al., 2018). Cameron et al. reported a case of BRA in which a total of ten amnioinfusions were performed between 17 and 33 weeks' gestation (Cameron et al., 1994). Chorioamnionitis led to preterm delivery at 33 weeks. The infant had no significant pulmonary hypoplasia nor any of the compression effects usually associated with the oligohydramnios sequence. Peritoneal dialysis was provided for the infant with a long-term aim of eventual renal replacement therapy, but dialysis was unsuccessful and the infant died at 23 days of age. Bienstock et al. reported a case of a 34-year-old woman, gravida 1 para 0, who presented at 23 $\frac{5}{7}$ weeks of gestation with a diagnosis of anhydramnios and a female fetus with BRA (Bienstock et al., 2014). The patient underwent weekly serial amnioinfusion with the goal of improving fetal pulmonary development. At 28 weeks' gestation, the patient delivered a live newborn who required minimal respiratory support. The neonate at the time of the case report was 9 months of age and undergoing daily peritoneal dialysis. At the present time, these types of prenatal procedures should be deemed experimental interventions in cases of BRA, and such management can only be undertaken with the oversight of the institutional review board (IRB) and full disclosure of the risks to the expectant mother and the fetus (Polzin, 2017; Sugarman et al., 2018).

Unilateral Renal Agenesis

URA is a condition in which an individual is born with a nonectopic, solitary functioning kidney (SFK) and failure of the contralateral kidney to develop. URA occurs in 1 in 1200 live births. Renal agenesis is most often an isolated event that occurs sporadically, however in a few instances it is actually secondary to an identifiable chromosomal abnormality or as part of a constellation of developmental defects, such as VATER (vertebral, anorectal, tracheoesophageal, renal) or MURCS (Müllerian duct aplasia, uterine hypoplasia, renal aplasia, cervicothoracic somite dysplasia). **Complete absence of one kidney occurs more frequently than BRA but is not easily detected on physical examination and is usually an incidental finding during an imaging study.** The largest study to date of neonates with an isolated single umbilical artery did not find an increased incidence of URA or other malformations (Deshpande et al., 2009). URA may remain undetected unless examination of the external genitalia and/or radiographic evaluation of the female or male pelvis for other reasons shows an anomaly associated with renal agenesis. **Since the mid-1990s, prenatal ultrasound examinations have been performed more routinely, and URA has been detected with increased frequency** (Sipek et al., 1997). **A substantial number of cases thought to be URA were a dysplastic kidney or MCDK that had involuted before birth (5%)** (Hiraoka et al., 2002: Schreuder et al., 2009). MCDK has an incidence of 1 in 4300. Renal aplasia is found in 1 in about 1300 births, which is similar to the incidence of renal agenesis and may be the most common cause of congenital solitary kidney. Renal aplasia includes those units with rudimentary parenchyma and ureter. It is thought to be a result of early regression of the ureteric bud, altered metanephric differentiation, or defects in the reciprocal induction of the branching ureteric duct and the metanephric blastema. Curvilinear calcifications on a plain radiograph or computed tomography (CT) scan are a sign of a previous MCDK that may have involuted and not a true URA (Nakano et al., 1996). **A plain radiograph of the abdomen supports this diagnosis if the splenic or hepatic flexure of the bowel is in its normal location and not in the ipsilateral renal fossa, suggesting that a dysplastic kidney or MCDK may have formed in the renal fossa before involuting** (Matsell, 1998). A flattened adrenal gland or the spleen (on the left) may be mistaken for a kidney on the 20-week structural ultrasound (Woolf and Hillman, 2007).

Incidence

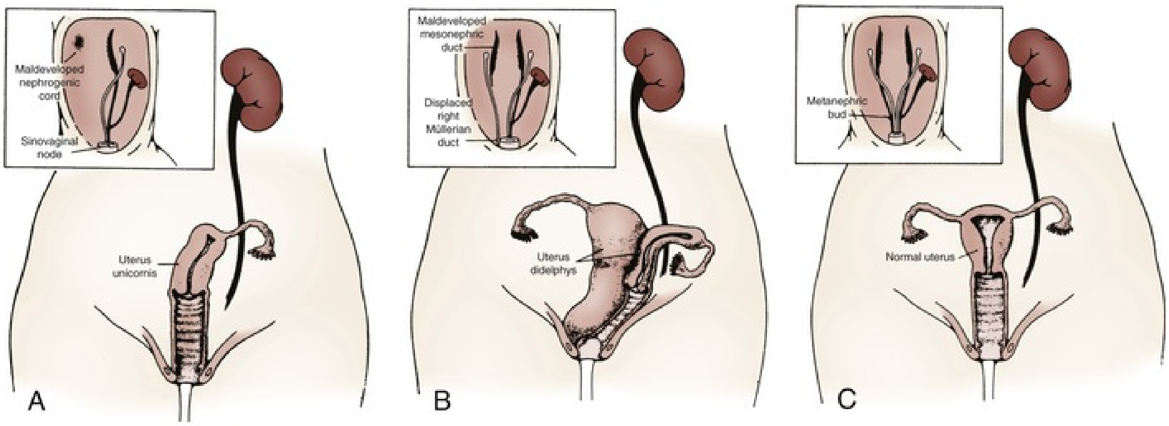
Most autopsy series suggest that URA occurs in 1 of 1100 births (Doroshow and Abeshouse, 1961). Ultrasound screening of 280,000 schoolchildren in Taipei showed the incidence of URA to be 1 in 1200 (Sheih et al., 1990). The high male predominance of BRA is not nearly as striking in the unilateral condition, with a **male-to-female ratio of 1.8 : 1** (Doroshow and Abeshouse, 1961). **Absence of a kidney occurs somewhat more frequently on the left side, and a familial tendency for renal agenesis has been noted** (Cascio et al., 1999). McPherson et al. concluded that inheritance of URA was autosomal dominant with a 50% to 90% penetrance (McPherson et al., 1987). Others who evaluated families with more than one affected individual have confirmed this inheritance pattern (Roodhooft et al., 1984; Battin et al., 1993). Screening recommendations are similar to those for UR (see the Bilateral Renal Agenesis section earlier in this chapter).

Genetic/Syndromic and Other Associations

An absent kidney has been noted in a number of genetic disorders in which there is a deletion of several chromosomal loci: 8q13.3 (Pierides et al., 2002; Dowton et al., 1997), 22q11 (Stewart et al., 1999), and in X-linked and sporadic cases of Kallmann syndrome (Quinton et al., 2001). Several syndromes have been associated with URA, including Turner syndrome, Poland syndrome (Mace et al., 1972), Fraser syndrome (Fryns et al., 1997), branchio-oto-renal (BOR) syndrome (Pierides et al., 2002), and DiGeorge anomaly. Maternal diabetes is associated with a threefold increased risk for renal agenesis and dysplasia (Davis et al., 2010). Animal studies have shown that the developing kidney is adversely affected by a high glucose environment, causing dysmorphogenesis of the metanephros and ureteric bud and disruptions in the normal process of nephrogenesis resulting in a reduced population of nephrons (Kanwar et al., 2005; Cunha et al., 2008). About 30% of children with the VACTERL association (vertebral, imperforate anus, cardiac, tracheoesophageal atresia, renal, and limb anomalies) have URA (Kolon et al., 2000). Children with supernumerary nipples (Urbani and Betti, 1996) and disorders of the ears with hearing loss, especially if it is congenital (Huang et al., 2001), and preauricular pits (Pierides et al., 2002), have been thought to have an increased incidence of URA. Studies have not shown a significant relationship between preauricular pits, minor ear tags, and URA (Arora and Pryce, 2004; Deshpande and Watson, 2006). A renal sonogram is recommended when these ear anomalies are found in the presence of other malformations. In addition, when more than one congenital anomaly is present (e.g., ventricular septal defect and an undescended testis) a renal sonogram is prudent, but when specific complexes of anomalies associated with renal agenesis are present (e.g., VACTERL-associated anomalies), a comprehensive radiographic examination of all organ systems including the spine is mandatory.

Embryology

The embryologic basis for URA and BRA is thought to be similar, and it is most likely caused by abnormalities in the development and/or function of the UB. This observation is supported by the increased incidence of *RET* mutations documented in humans with renal agenesis (Skinner et al., 2008; Davis et al., 2014). Complete absence of a ureteric bud or aborted ureteral development prevents reciprocal induction of the metanephric blastema, which is critical for development into the definitive adult kidney. The metanephros is not likely to be responsible for the majority of cases, because the ipsilateral gonad (derived from adjacent mesenchymal tissue) is rarely absent, malpositioned, or nonfunctioning (Ashley and Mostofi, 1960). **The high incidence of absent or malformed proximal WD structures in the male and anomalies of the MD structures in the female suggest that the embryologic insult affects the UB primarily in its early development and influences the development of WD derivatives.** The abnormality most likely occurs no later than 4 or 5 weeks' gestation, when the UB forms and the WD begins to develop into the ejaculatory duct, seminal vesicle, and vas deferens. The MD in the female begins its medial migration at this time, crossing over the WD (sixth week) during its differentiation into the fallopian tube, uterine horn and body, and proximal vagina (Yoder and Pfister, 1976). **Magee et al. proposed an embryologic classification to explain the association of URA and MD anomalies (Fig. 38.3)** (Magee et al., 1979).



Maldeveloped nephrogenic cord
Sinovaginal node
Uterus unicornis
A
Maldeveloped mesonephric duct
Displaced right Müllerian duct
Uterus didelphys
B
Metanephric bud
Normal uterus
C

FIG. 38.3 A proposed categorization of genital and renal anomalies in females. See text for details. (From Magee MC, Lucey DT, Fried FA. A new embryologic classification for uro-gynecologic malformations: the syndromes of mesonephric duct induced Müllerian deformities. *J Urol*. 1979;121:265–267.)

- In type I URA, the insult occurs before the fourth week of gestation, and there is nondifferentiation of the urogenital ridge structures, including the MD and WD. If unilateral, a uterus consisting of a single MD (unicornuate uterus) will form and will be associated with contralateral renal agenesis.
- In type II URA, the insult occurs early in the fourth week of gestation, affecting both the WD and the UB. Because it is critical that the MD maintains close contact with the WD for MD elongation and subsequent fusion, maldevelopment of the WD affects renal development, MD elongation, contact with the urogenital sinus, and subsequent fusion. Therefore, a didelphys uterus will form with obstruction of the horn and vagina on the side of the URA.
- Finally, in type III URA, the insult occurs after the fourth week of gestation, and the WD and MD elongation and differentiation proceed normally. In this case, only the UB and metanephric blastema are affected, thereby resulting in isolated URA.

Associated Genitourinary and Adrenal Anomalies

Unilateral renal agenesis is usually asymptomatic and often identified on prenatal testing, whereas in the past it was commonly an incidental autopsy finding. The most commonly associated urologic comorbidity is vesicoureteral reflux for both genders, and in females there may also be Müllerian structure abnormalities (Savvidou and Dhillon, 2014). **The ipsilateral ureter is absent in about 60% of cases with URA** (Ashley and Mostofi, 1960). In this series, 19 of 232 with URA had only a portion of the lower end of the ureter present. In most cases of complete absence of the ureters, the bladder showed no evidence of a ureteric orifice with failure of the ipsilateral trigone to develop (Ashley and Mostofi, 1960). Cell lineage studies using a murine model show that the trigone has a urogenital sinus origin and should form normally (Viana et al., 2007; Mendelsohn, 2009). The trigone may not be distinguishable from the surrounding detrusor when the intramural ureter is absent. Therefore, the endoscopic appearance of the trigone in this setting has led to the probable misnomer in the case of the "hemitrigone" (in association with complete ureteral agenesis) or "asymmetrical trigone" (in the presence of a partially developed ureter). Except for ectopia or malrotation, anomalies of the contralateral kidney are infrequent (Chow et al., 2005). **However, abnormalities of the contralateral ureter are not uncommon, including ureteropelvic and ureterovesical junction obstruction in 11% and 7%, respectively** (Cascio et al., 1999), **and reflux in 30%** (Atiyeh et al., 1993; Cascio et al., 1999).

Although the ipsilateral adrenal gland may be flattened (Hoffman et al., 1992), adrenal agenesis occurs in less than 10% of URA cases (Ashley and Mostofi, 1960) and in 17% of individuals with URA undergoing a CT scan (Kenney et al., 1985). Genital anomalies occur much more frequently. The incidence of a reproductive tract malformation for both genders varies from 20% to 40% (Thompson and Lynn, 1966). **Despite the predominance of males with URA, reproductive tract abnormalities in females occur in at least 25% to 50% of cases compared with 10% to 15% in males. Regardless of sex, both gonads are usually normal.** Therefore, the different phenotypes that occur with URA may result from a primary urogenital ridge defect, which explains the finding of gonadal and adrenal agenesis only in the minority of cases, or a primary defect in the development of the UB and WD, which leads to the more common cases of URA and frequently observed abnormalities of the WD, MD, and their derivatives.

Anomalies in the Male

The testis and head of the epididymis, which contain the efferent ductules

derived from the mesonephric tubules, are invariably present; all structures proximal to that point, which develop from the WD (the body and tail of the epididymis, vas deferens, seminal vesicle, ampulla, and ejaculatory duct), are absent in almost 50% of cases with URA (Ochsner et al., 1972). Donohue and Fauver reported that 79% of adult males with an absent vas deferens have an absent ipsilateral kidney; left-sided lesions predominated, with a ratio of 3.5 : 1 (Donohue and Fauver, 1989). However, bilateral absence of the vas has been noted with URA (McCallum et al., 2001). Occasionally, the WD structures are rudimentary or ectopic rather than absent (Holt and Peterson, 1974). Ipsilateral cryptorchidism rarely occurs. A seminal vesicle cyst caused by obstruction (atresia) of the ejaculatory duct may be seen in association with ipsilateral renal agenesis, and it has been referred to as Zinner syndrome (Pereira et al., 2009). Six cases (5%) were noted among 119 boys found to have URA during ultrasound screening (Sheih et al., 1990). Pelvic sonography or magnetic resonance imaging (MRI) in boys diagnosed with URA may demonstrate a seminal vesicle cyst (van den Ouden et al., 1998; Seo et al., 2009). In cases of seminal vesicle cysts and URA, the ureter may insert into the prostatic urethra or seminal vesicle. Cystic dysplasia of the rete testis is a rare benign condition that is often associated with ispsilateral renal anomalies, most commonly URA, and spontaneous regression and conservative treatment in the setting of WD defects have been reported (Jeyaratnam and Bakalinova, 2010). In males evaluated for infertility, the diagnosis of URA should be suspected when the vas deferens or body and tail of the epididymis are impalpable. In children, URA should be considered when vasal and/or epididymal anomalies are incidentally found at the time of scrotal ultrasonography, herniorrhaphy, or orchiopexy.

Anomalies in the Female

A variety of anomalies may result from incomplete MD formation because of alterations in normal WD development. Approximately one-fourth to one-third of women with URA have an abnormality relating to WD development (Thompson and Lynn, 1966; Heinonen, 2004; Friedman et al., 2018). Conversely, 43% of women with internal genital anomalies have URA (Semmens, 1962; Heinonen, 1997). The most common MD anomalies are a unicornuate uterus with complete absence of the ipsilateral horn and fallopian tube or a bicornuate uterus with rudimentary development of the horn on the affected side (Candiani et al., 1997). The fimbriated end of the fallopian tube, however, is usually fully formed and is analogous to the head of the epididymis in the male (Shumaker, 1938). Partial or complete midline fusion of the MD may result in a double (didelphys) or septate uterus with either a single or a duplicated cervix. Complete duplication or separation of the vagina, proximal vaginal atresia associated with a small introital dimple, and complete absence of the vagina have been reported. Obstruction of one side of a duplicated system is not uncommon, and unilateral hematocolpos or hydrocolpos associated with a pelvic mass and/or pain has been described in pubertal girls and has been previously referred to as the Herlyn-Werner-Wunderlich syndrome (Yoder and Pfister, 1976); (Tong et al., 2013). **Smith and Laufer** (Smith and Laufer, 2007) **suggested the acronym OHVIRA to classify the syndrome of *O*bstructed *H*emi*V*agina and *I*psilateral *R*enal *A*nomaly.** In rare instances, this anomalous condition has been mistaken for a large or infected Gartner duct cyst. Sometimes a Gartner duct cyst has been found in a prepubertal girl with an ectopic ureter that is blind ending proximally or one that is connected to a rudimentary kidney (Currarino, 1982). A total of 6% of girls with URA were found to have a Gartner cyst on mass screening of schoolchildren (Sheih et al., 1990). Infertility occurs in as many as 33% of affected women with renal agenesis and unicornuate uterus (Heinonen, 1997). When anomalies of the uterus, including congenital absence of the uterus, unicornuate uterus, and didelphic uterus, are found on ultrasonography or MRI, radiologic investigation of the urinary tract often demonstrates URA or other renal anomalies (Reichman and Laufer, 2010). Based on review of existing literature, Friedman et al. advocated for pelvic ultrasound as a screening tool after thelarche but before menarche to identify Müllerian anomalies in patients with URA (Friedman et al., 2018).

Another anomaly often associated with URA is the Mayer-Rokitansky-Küster-Hauser syndrome (MRKH), which is a complex of malformations occurring in 1 of 4500 newborn females (Guerrier et al., 2006; Oppelt et al., 2012; Pizzo et al., 2013). This syndrome includes not only renal anomalies, but also genital tract anomalies ranging from upper vaginal atresia to total Müllerian agenesis in an otherwise phenotypically normal 46,XX female. There are two main subtypes. Type I is the typical form characterized by the finding of only symmetrical muscular buds or Müllerian remnants and normal fallopian tubes. Type II, which is more common but considered the atypical form, is characterized by asymmetrical hypoplasia of one or two buds with or without dysplasia of the fallopian tubes. Most importantly, the atypical form is often associated with renal anomalies, primarily URA, ectopia of one or both kidneys, or horseshoe kidney in about 40% to 60% (Guerrier et al., 2006). Duncan et al.

reported on the most severe constellation of malformations and referred to this as the MURCS association; this includes Müllerian duct aplasia (96%), renal aplasia or ectopia (86%), and cardiothoracic somite dysplasia (two to four anomalous vertebrae between C5 and T1 [80%]) Duncan et al., 1979).

Anomalies of Other Organ Systems

Dursun et al. found that 44% of individuals with a congenital solitary kidney had various nongenitourinary anomalies including cardiovascular (15%), gastrointestinal (9%), neurologic (3%), and hematologic (6%) (Dursun et al., 2005).

Diagnosis and Radiographic Evaluation

About 90% of fetal kidneys associated with a contralateral URA or MCDK undergo compensatory hypertrophy in utero from 20 weeks' gestation (van Vuuren et al., 2012). Postnatally, retroperitoneal ultrasonography with color Doppler will show an absence of the kidney and ipsilateral renal vessels (see Fig. 38.1). The diagnosis of URA usually can be confirmed with a radionuclide DMSA scan showing absent uptake of the isotope on one side, with the contralateral kidney often showing compensatory hypertrophy. A DMSA scan will also detect an ectopic (usually pelvic) or a crossed ectopic kidney in cases in which the nonvisualized orthotopic kidney is thought to be absent (Volkan et al., 2003). In some cases, crossed fused ectopia may be difficult to distinguish from a congenital solitary kidney that has undergone compensatory hypertrophy or a solitary complete duplication. A small dysplastic kidney or MCDK may be misdiagnosed as URA when a kidney is not seen on ultrasonography (Mesrobian et al., 1993). When a fetus with other suspected organ anomalies undergoes MRI, an absent kidney can be confirmed (Dell'Acqua et al., 2002). **When URA is diagnosed, especially in infants and young children, a voiding cystourethrogram may be performed because there is a 28% incidence of contralateral reflux (Kaneyama et al., 2004).**

Special Considerations

The most common question many parents of a child with URA ask is "Will having only one kidney affect my child's life, and will there be any restrictions on the child's activities?" **Psooy summarized several North American studies, which suggest that whereas bicycling, sledding, downhill**

skiing/snowboarding, and equestrian activities are the more common causes of renal injury, motor vehicle accidents as passenger and pedestrian result in more renal trauma than sports activities (Psooy, 2009). In addition, these sports activities have more than a fivefold relative risk for head injury compared with renal injury. Psooy noted that children are generally not restricted from these activities just because they have "only one head" (Psooy, 2009). Rice and the American Academy of Pediatrics Council on Sports Medicine and Fitness advise that each athlete needs individual assessment for his or her particular sport and that wearing protective padding may reduce the risk for injury to the solitary kidney, thus allowing participation in most sports (Rice and American Academy of Pediatrics Council on Sports Medicine and Fitness, 2008). Since those recommendations were proposed (Grinsell et al., 2012) used data from the National Athletic Trainers' Association High School Injury Surveillance Study, which calculated the rates for sport-specific injuries to select organs. Although more than 4.4 million athlete-exposures, defined as 1 athlete participating in 1 game or practice, and 23,666 injuries were reviewed, only 18 kidney injuries (3 lacerations and 15 contusions) occurred, none of which were catastrophic or required surgery. **So, in summary, having a solitary kidney does not preclude an individual from safely participating in sports and athletic activities.**

Prognosis

In the past, there was no definitive evidence that having a congenital solitary kidney predisposed to long-term problems when compared with outcomes of individuals undergoing nephrectomy for Wilms tumor or donor nephrectomy (Shapiro et al., 2003). It is now well recognized that the latter two groups represent completely different conditions compared with the congenital solitary kidney group in which genetic or environmental events may have altered the development of both kidneys, impacting growth and function throughout life. The remaining kidney is thought to be healthy in living kidney donors who have lower rates of end-stage renal failure (ESRF) than the general population or those undergoing nephrectomy for tumor in childhood (Ibrahim et al., 2009).

Current Concepts Regarding Prognosis in Adults With Unilateral Renal Agenesis

Several studies examine the long-term outcome of children with SFK, although there are no definitive conclusions. These studies are based on the "hyperfiltration hypothesis" of Brenner et al. (Brenner et al., 1996). In their rodent model, unilateral nephrectomy led to hyperfiltration of the remnant nephrons and altered sodium balance with subsequent glomerular hypertension. These hemodynamic changes resulted in glomerular damage with albuminuria and glomerulosclerosis. The hyperfiltration hypothesis may be extrapolated to individuals with SFK who have reduced nephron number, especially when the solitary kidney is also affected by CAKUT (Westland et al., 2012, 2013a). The CAKUT spectrum includes renal agenesis, renal hypoplasia or dysplasia, MCDK, ureteropelvic junction (UPJ) obstruction, megaureter, posterior urethral valves, and vesicoureteral reflux, and occurs in about 1 in 600 births (Wiesel et al., 2005), and it is found in 20% of those with chromosomal abnormalities (Garne et al., 2009). About 10% of those with CAKUT have close relatives with renal abnormalities, but most are asymptomatic (Bulum et al., 2013). **There is now evidence that subtle defects in UB branching can cause reduced nephron number, which may lead to renal disease later in life** (Brenner and Mackenzie, 1997; Costantini and Shakya, 2006; Chevalier, 2009).

In humans, there is an eightfold range in the normal variation of the actual number of glomeruli, ranging from 200,000 to 1.8 million (Hughson et al., 2003). Therefore it is more likely for an individual with nephron numbers at the lower end of the spectrum to be at greater risk for renal insufficiency at any age and from any etiology (Luyckx and Brenner, 2010). Luyckx et al. proposed clinical surrogates for low nephron number and susceptibility to hypertension and renal disease in humans (Luyckx et al., 2013). They included low birth weight, preterm birth, short stature, reduced kidney volume by ultrasonography, low kidney mass by scintigraphy, glomerulomegaly by biopsy, gene polymorphisms (PAX2, RET), and infants of diabetic mothers.

Prenatal renal development may be affected by medications including ACE inhibitors, dexamethasone, antiepileptic medications, aminoglycosides, and IUGR and maternal diabetes. In the past, studies of renal survival in children with CAKUT have been difficult to perform because they involve decades of follow-up, and the phenotypes of these disorders are not uniform (Pope et al., 1999). Sanna-Cherchi et al. evaluated the long-term functional outcomes in individuals with CAKUT, including those with URA from a single pediatric nephrology center (Sanna-Cherchi et al., 2009). A total of 312 patients with CAKUT who had a known defect of the number or size of at least one kidney were followed up for as long as 20 years. Patients with isolated vesicoureteral reflux and duplications were excluded. Dialysis-free survival was evaluated, taking into consideration reflux, age at diagnosis, hypertension, proteinuria, and serum creatinine. Six subgroups were examined, including URA, unilateral and bilateral renal hypoplasia, posterior urethral valves, MCDK, and horseshoe kidney. These investigators found that by 30 years of age, 19% of all patients were on dialysis, most of whom had posterior urethral valves, bilateral renal hypoplasia, or URA. Further analysis showed that patients with a solitary kidney had a 50% probability of requiring dialysis by 30 years of age. Notably, most patients with URA in this study were diagnosed during adolescence and had a normal creatinine level at the time of diagnosis. Interestingly, the patients diagnosed at birth had a slightly elevated creatinine level (0.68 mg/dL). These and other studies point to the fundamental differences in individuals with URA and adults who undergo unilateral nephrectomy. The number of nephrons in children with URA may be abnormally low, and those with fewer nephrons may be at greater risk for developing hypertension, albuminuria, and focal glomerulosclerosis, and ultimately progressing to ESRD.

The KIMONO (Kidney of Monofunctional Origin) study retrospectively evaluated 116 children with congenital or pSFK (primary SFK), 54 with URA, 62 with MCDK, and 90 with sSFK (secondary SFK after unilateral nephrectomy for CAKUT or tumor) (Westland et al., 2011). About 30% had ipsilateral CAKUT (the side of the SFK only) in both groups. Renal injury was defined as hypertension and/or albuminuria and/or the use of renoprotective medication. **Of all children with SFK, 32% had renal injury at a mean age of 9.5 years.** GFR declined as early as 9 years of age, and microalbuminuria developed at about 16 years of age. As expected, children with ipsilateral CAKUT, involving pSFK or sSFK, had more renal injury than those in either group without CAKUT. Although the results of the KIMONO study are similar to those of Sanna-Cherchi et al., the study did not consider the different molecular origin(s) and clinical course of the different conditions of each patient. The estimates of renal injury and the proportion of patients who develop ESRD are most likely overestimated because of several factors including selection bias.

Calderon-Margalit et al. conducted a nationwide, population-based cohort study of over 1 million Israeli adolescents who were examined before compulsory military service and linked this information to the Israeli ESRD registry (Calderon-Margalit et al., 2018). Although only 1% of patients with a history of CAKUT, pyelonephritis, or glomerular disease in childhood, with no apparent sequelae in adolescence, developed ESRD during 30 years of follow-up. The risk in such patients was approximately four times as high as the risk among participants who had no such history. The association between CAKUT and the risk for ESRD in adulthood was similar in magnitude to other renal diseases identified in childhood such as pyelonephritis or glomerular diseases. This study, along with the KIMONO study and the study by Sanna-Cherchi et al. (Sanna-Cherchi 2009), underscores the importance of identifying individuals who are more likely to progress to chronic renal failure in adulthood and ensuring appropriate long-term follow-up.

Current suggestions for children with SKF include annual assessments of blood pressure and microalbuminuria (first morning specimen) when there is no CAKUT and biannually when there is CAKUT, because hypertension and microalbuminuria (>30 mg/24 h) are hallmarks of progressive decrease in glomerular filtration rate (Hegde and Coulthard, 2009; Westland et al., 2013a, 2014).Treatment with an ACE inhibitor may be indicated to slow the progression of renal injury (Puddu et al., 2009). Depending on the age of the patient, dietary changes may also be recommended, including limiting salt and avoiding excessive protein intake. Blood pressure, urinary albumin, and serum creatinine are monitored 2 to 4 times per year when the GFR less than 60 mL/min/1.73 m^2 or the individual is taking medication for hypertension or proteinuria (Westland et al., 2013b, 2014). In addition, periodic ultrasonography is performed for both pSFK and sSFK, especially with CAKUT to assure appropriate compensatory hypertrophy and or growth into adolescence. For those with GFR greater than 60 mL/min/1.73 m^2 who are not on medication, serum creatinine can be performed every 5 years (Westland et al., 2014).

Supernumerary Kidney

Occasionally, there will be more than two kidneys detected within an individual; the additional kidney(s) are called *supernumerary* kidneys (in excess of the normal number). **The supernumerary kidney is truly an accessory organ with its own collecting system, blood supply, and distinct encapsulated parenchymal mass.** Three or more separate kidneys can form with the additional renal units usually being smaller. The two main kidneys are commonly functionally normal, equal in size, and orthotopically located. The supernumerary kidney may be either totally separate from the normal kidney on the same side or connected to it by loose areolar tissue (Geisinger, 1937). The ipsilateral ureters may be bifid or completely duplicated. The condition is not analogous to a single kidney with ureteral duplication in which the collecting systems drain portions of one parenchymatous mass surrounded by a single capsule.

Incidence

The true incidence of this anomaly cannot be determined because only about 100 cases have been reported (McPherson et al., 1987). It affects males and females equally but has a higher predilection for the left side (N'Guessan and Stephens, 1983). Four cases of bilateral supernumerary kidneys have been reported (Oto, Kerimoglu et al. 2002).

Embryology and Molecular Mechanisms Involved in Development of a Supernumerary Kidney

A second UB or a branching from the initial UB appears as a necessary first step. Next, the nephrogenic anlage may divide into two metanephric tails, which separate entirely when induced to differentiate by the separate or bifid UBs (N'Guessan and Stephens, 1983). The two metanephroi develop only after being penetrated by the bifid or separate UBs. Kidney development is initiated when a single UB forms from the WD in response to GDNF secreted by the adjacent metanephric mesenchyme. Posterior restriction of GDNF expression is critical for the development of a UB in the normal position, whereas another intercellular signaling system, including SLIT2 or its receptor ROBO2, is also important in ensuring that a single UB forms in the appropriate location. Grieshammer et al. showed that mutant mice lacking either SLIT2 or its receptor ROBO2 develop supernumerary UBs that are correlated with abnormal maintenance of GDNF expression in anterior MM (Grieshammer 2004). The SLIT2/ROBO2 intercellular signaling system restricts, directly or indirectly, the extent of the GDNF expression and plays a critical role in precisely positioning the site of kidney induction.

Description and Associated Anomalies

The supernumerary kidney is a distinct renal mass that may be either completely separate or only loosely attached to the major kidney on the ipsilateral side. **In about 60% of cases, it is located caudad to the dominant kidney, which is in its orthotopic position in the renal fossa**. When a separate and distinct ureter is present, the supernumerary kidney is more likely to be cranial to the dominant kidney but caudal to the adrenal gland (Bernik et al., 2001). The supernumerary kidney is reniform but generally smaller than the main ipsilateral kidney. In almost one-half of reported cases, the collecting system is severely dilated with thin parenchyma, suggesting obstruction to the outflow of urine. The ipsilateral and contralateral kidneys are usually normal. The ureteral interrelationships on the side of the supernumerary kidney can be variable. Convergence of the ipsilateral ureters distally to form a common stem and a single ureteral orifice occurs in 50% of cases (N'Guessan and Stephens, 1983), which suggests “a bud off of a bud” situation (Fig. 38.4). Two completely independent ureters, each with its own entrance into the bladder, are seen in the other 50% of cases (Fig. 38.5). The Weigert-Meyer principle is usually followed, but in 10% of cases, the caudal kidney has a ureter that does not follow the rule and enters the trigone below the ipsilateral ureter (Tada et al., 1981). Individual case reports have described calyceal communications between the supernumerary and the dominant kidney or fusion of the dominant kidney's ureter with the pelvis of the supernumerary kidney to create a single distal ureter that then enters the bladder (Kretschmer, 1929). The vascular supply to the supernumerary kidney is anomalous, depends on its position in relation to the major ipsilateral kidney, and should be separate to be considered a true supernumerary kidney (Fig. 38.6) (Kaneoya et al., 1989).

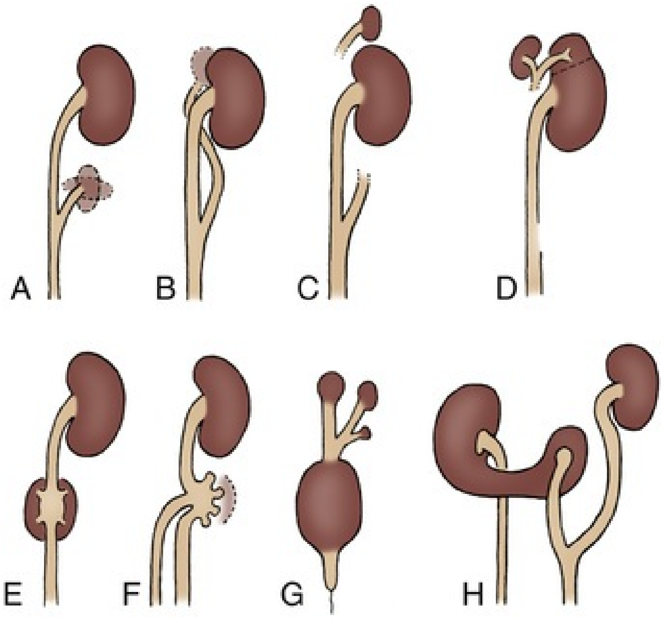


FIG. 38.4 (A to H) Various patterns of urinary drainage when ureters form a common stem. All kidney positions are relative only and are depicted on the left side for ease of interpretation. *Dashed lines* indicate that detail was not defined. (From N'Guessan G, Stephens FD. Supernumerary kidney. *J*

Urol. 1983;130:649–653.)

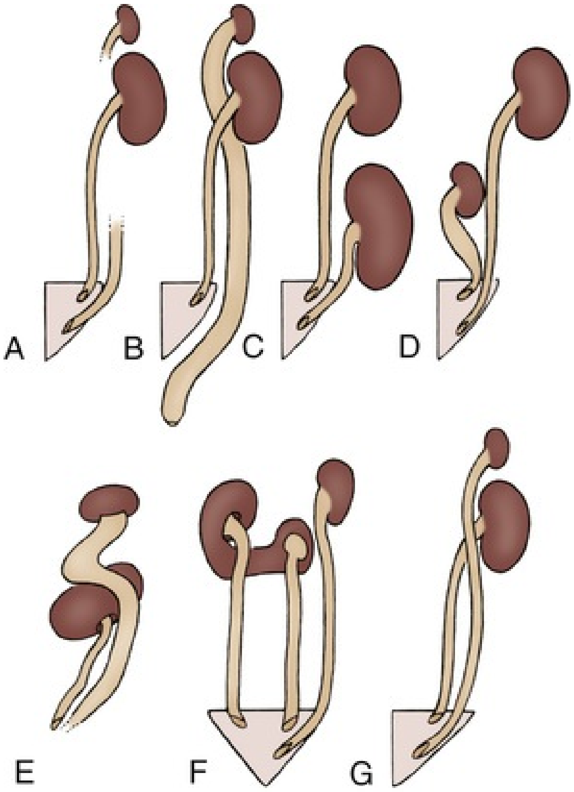

FIG. 38.5 (A to G) Various patterns of urinary drainage of supernumerary and ipsilateral kidneys when ureters are completely separated. All kidney positions are relative only and are depicted on the left side for ease of interpretation. *Dashed lines* indicate that detail was not defined. (From N'Guessan G, Stephens FD. Supernumerary kidney. *J Urol.* 1983;130:649–653.)

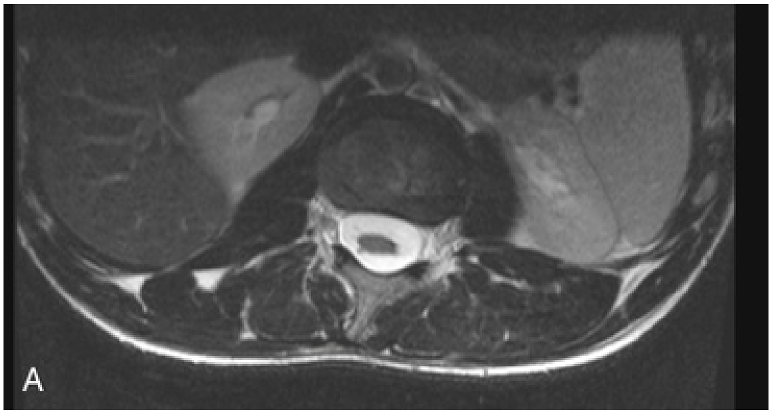

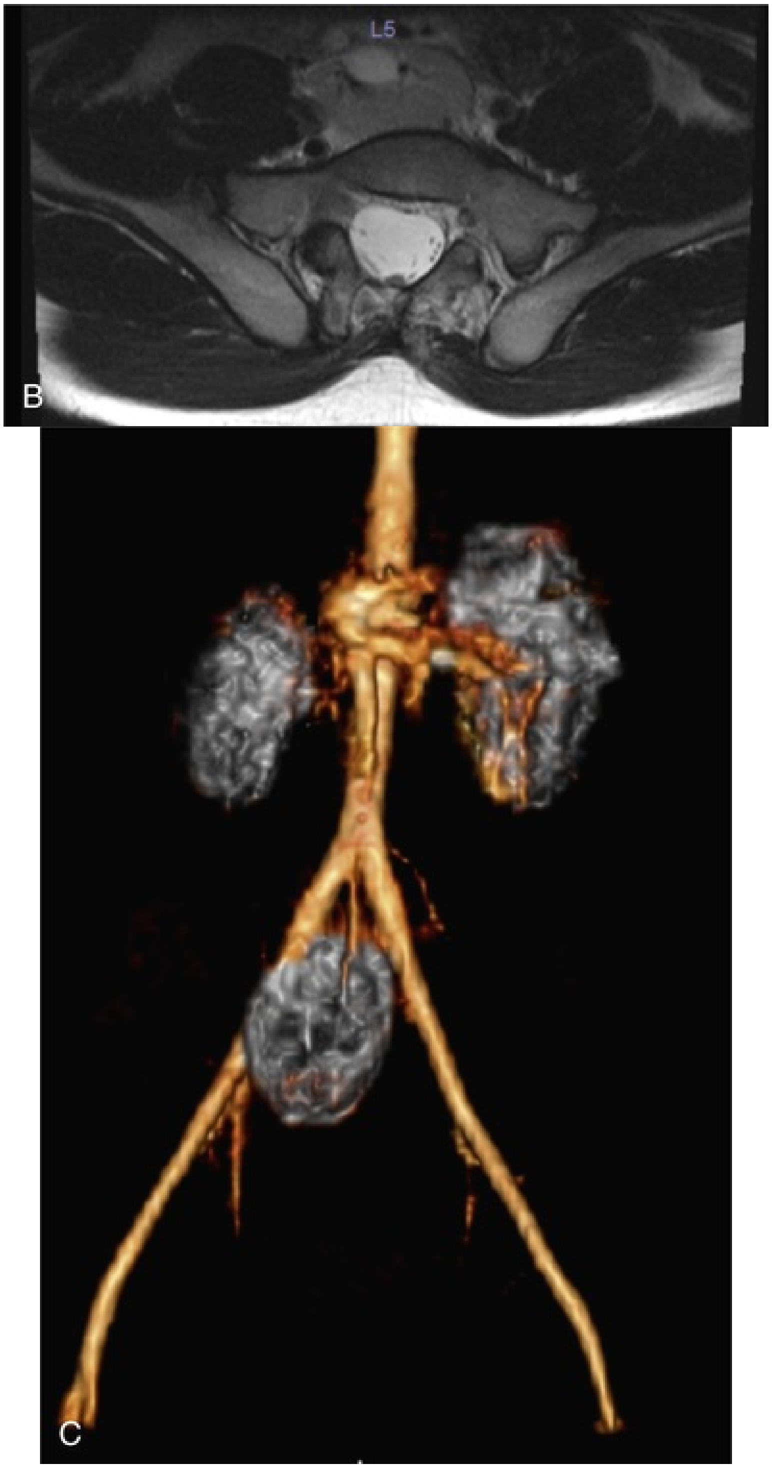

FIG. 38.6 A 12-year-old child with cloacal exstrophy. (A) Magnetic resonance (MR) axial images of bilateral orthotopic kidneys in a patient with supernumerary kidney. (B) MR axial images of pelvic supernumerary kidney overlying the sacrum. (C) Three-dimensional coronal reconstruction of MR images. Blood supply to the pelvic kidney is from the right internal iliac artery, and venous drainage is into the inferior vena cava.

Associated Symptoms

This anomaly is rarely symptomatic, but it may become symptomatic in early adulthood. The average age at diagnosis is 36 years. Pain, fever, hypertension, and a palpable abdominal mass are the usual presenting complaints. Urinary infection, obstruction, or both, are the major conditions that lead to evaluation. Ureteral ectopia from the supernumerary kidney may produce urinary incontinence, but this is extremely rare. A palpable abdominal mass secondary to a carcinoma in the supernumerary kidney has been described in two patients. In 25% of all reported cases, the supernumerary kidney is discovered only at autopsy (Carlson, 1950).

Diagnosis

If the supernumerary kidney is normal and asymptomatic, it is usually diagnosed when radiographic studies are performed for other reasons. The kidney may be inferior and distant enough from the ipsilateral kidney so that it does not alter the position of the normal kidney (Conrad and Loes, 1987). If it is in close proximity, it may displace the predominant kidney or its ureter very slightly. A supernumerary kidney may become symptomatic because of obstruction from a stone (Koureas et al., 2000). In this case, ultrasonography may demonstrate distortion of the normal ipsilateral kidney and ureter. If the collecting system is bifid, the dominant kidney on that side will usually be involved in the same disease process. If the ureters are separate, the ipsilateral kidney may show the effects of an abnormal supernumerary kidney. Magnetic resonance urography (MRU) and retrograde pyelography may be needed to delineate the anomaly. Radionuclide imaging provides information about relative function in the supernumerary and the normal kidneys (Conrad and Loes, 1987). Cystoscopy reveals one or two ureteral orifices on the ipsilateral side, depending on whether the ureters are completely duplicated. Ureteral ectopia may exist in or outside the bladder. Occasionally, a supernumerary kidney is not accurately diagnosed until the time of surgery or at autopsy, or it may mimic a duplication (Kaneoya et al., 1989).

Key Points: Anomalies of Renal Number

- BRA is rare, estimated at 1 in 5000 births, and is almost always incompatible with life because of associated pulmonary hypoplasia.

- URA occurs in 1 in 1200 births. It predominates in males and occurs more frequently on the left side.
- Despite the predominance of males with URA, Müllerian duct abnormalities occur in 25% to 50% of cases of females with URA compared with WD anomalies in 10% to 15% of males with URA.
- Patients with solitary kidney carry a risk for CKD.
- The supernumerary kidney is a definitive accessory organ with its own blood supply and encapsulated parenchyma. The ureteral interrelationships on the side of the supernumerary kidney can be variable.

Anomalies of Renal Ascent

Simple Renal Ectopia

The fetal kidney ascends to its usual location from its origin in the pelvis in a predictable timeframe during gestation. The UB arises from the WD at the end of the fourth week, grows cranially toward the urogenital ridge, and acquires a cap of metanephric blastema by the fifth week. This unit of metanephric tissue and UB migrate cephalad while simultaneously rotating medially on its long axis. **The entire process of renal ascent is completed between 6 and 9 weeks' gestation so that the kidney resides in its usual location in the lumbar retroperitoneum below the adrenal glands.** The precise mechanism for this ascent remains unknown, and a detailed discussion of the molecular mechanisms involved in UB outgrowth and metanephric interactions is presented elsewhere in this textbook (see Chapter 20).

When the mature kidney fails to reach its normal location, the condition is known as *renal ectopia*. The term is derived from the Greek words *ek* ("out") and *topos* ("place"), and it literally means "out of place." An ectopic kidney can be found in one of the following positions: pelvic, iliac, abdominal, thoracic, and contralateral or crossed. There have been many purported factors that may influence the orderly ascent and rotation of the kidneys. Speculations have included UB maldevelopment (Campbell, 1930), defective metanephric tissue that fails to induce ascent (Ward et al., 1965), genetic abnormalities, and maternal illnesses or teratogenic causes (Malek et al., 1971). A vascular barrier that prevents upward migration secondary to persistence of the fetal blood supply has also been postulated (Baggenstoss, 1951), but the existence of an "early" renal blood supply does not prevent the affected kidney's movement to its ultimate position. The aberrant blood supply is probably an observed end result, not the cause, of the renal ectopia.

Incidence

The reported incidence of renal ectopia among autopsy series varies from 1 in 500 (Campbell, 1930) **to 1 in 1200** (Bell, 1946a), **with an average occurrence of about 1 in 900. There is no significant gender difference, and the left side is favored slightly over the right side** (Abeshouse and Bhisitkul, 1959). A solitary ectopic kidney occurred in 1 of 22,000 autopsies (Delson, 1975; Stevens, 1937). Sheih et al. performed a screening study for renal anomalies in schoolchildren and found that approximately 1 in 4000 had the renal anomaly categorized as renal ectopia (Sheih et al., 1989). A screening study in a Kenyan population of residents older than 2 years of age revealed simple renal ectopia in 0.35% (approximately 1 in 300) of the screened population (Magak et al., 2004). This rate is much higher than expected compared with other published rates, leading the authors to speculate either a common teratogenic exposure or genetic conditions. Bilateral ectopic kidneys are rarely observed and accounted for only 10% of all patients with renal ectopia in one study (Malek et al., 1971).

Description and Associated Anomalies

When ectopia occurs below the diaphragm, the classification of ectopia is based on the position of the kidney. The pelvic kidney lies opposite the sacrum, and the kidneys below the aortic bifurcation are the most common sites of ectopia; the lumbar kidney resides near the sacral promontory in the iliac fossa and anterior to the iliac vessels, and the abdominal kidney is above the iliac crest and is adjacent to the second lumbar vertebra (Fig. 38.7). The ectopic kidney typically is smaller than its orthotopic counterpart and, because of persistent fetal lobulations, may not conform to the usual reniform shape. Rotation of the kidney occurs during ascent of the kidney, and with renal ectopia representing an arrestment of ascension, the axis of the kidney is also frequently affected. **The renal pelvis is usually anterior (instead of medial) to the parenchyma, because the kidney has incompletely rotated.** The axis of the ectopic kidney may be slightly medial or vertical, but it may be tilted as much as 90 degrees laterally so that it lies in a true horizontal plane. **As a result of these anomalies of ascension and rotation, hydronephrosis is a common radiographic finding from a variety of causes.** Gleason et al. reported that hydronephrosis in renal ectopia resulted from obstruction in 50% of cases, either at the ureteropelvic or the ureterovesical junction (70% and 30%, respectively), 25% from reflux grade III or greater, and 25% from the malrotation alone (Gleason et al., 1994).

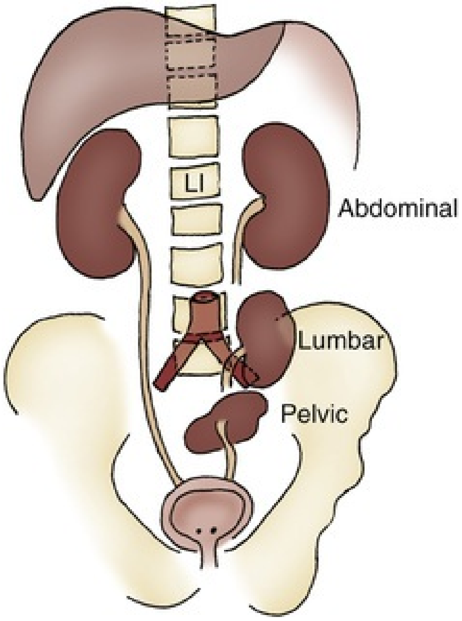

FIG. 38.7 Incomplete ascent of kidney. The kidney may halt at any level of its ascent from the pelvis. (From Gray SW, Skandalakis JE. The kidney and ureter. In: Gray SW, Skandalakis JE, eds. *Embryology for surgeons.* Philadelphia, PA: Saunders; 1972.)

Reflux has been reported in approximately 30% to 50% of children with ectopic kidneys when cystography is performed (Guarino et al., 2004; Dogan et al., 2017, Kramer and Kelalis, 1984). Vesicoureteral reflux occurs in either the ectopic kidney or orthotopic kidney. Guarino et al. observed that 86% of patients had reflux into the orthotopic kidney when reflux was also present in unilateral renal ectopia (Guarino et al., 2004). **The ureter associated with the ectopic renal unit usually enters the bladder on the ipsilateral side with its orifice positioned normally, except for those unusual cases with ectopic ureters** (Borer et al., 1998).

The arterial and venous network is frequently anomalous, and its vascular pattern depends on the ultimate position of the kidney (Dretler et al., 1971; Anson and Riba, 1939). There may be one or two main renal arteries arising from the distal aorta or from the aortic bifurcation, with one or more aberrant arteries emanating from the common or external iliac or even the inferior mesenteric artery. The kidney may be supplied entirely by multiple anomalous branches. **Exact delineation of the anomalous blood supply can be pursued with CT/MR imaging or formal angiography when necessary and can be helpful before surgical intervention (**Kara et al., 2011; Gülsün et al., 2000).

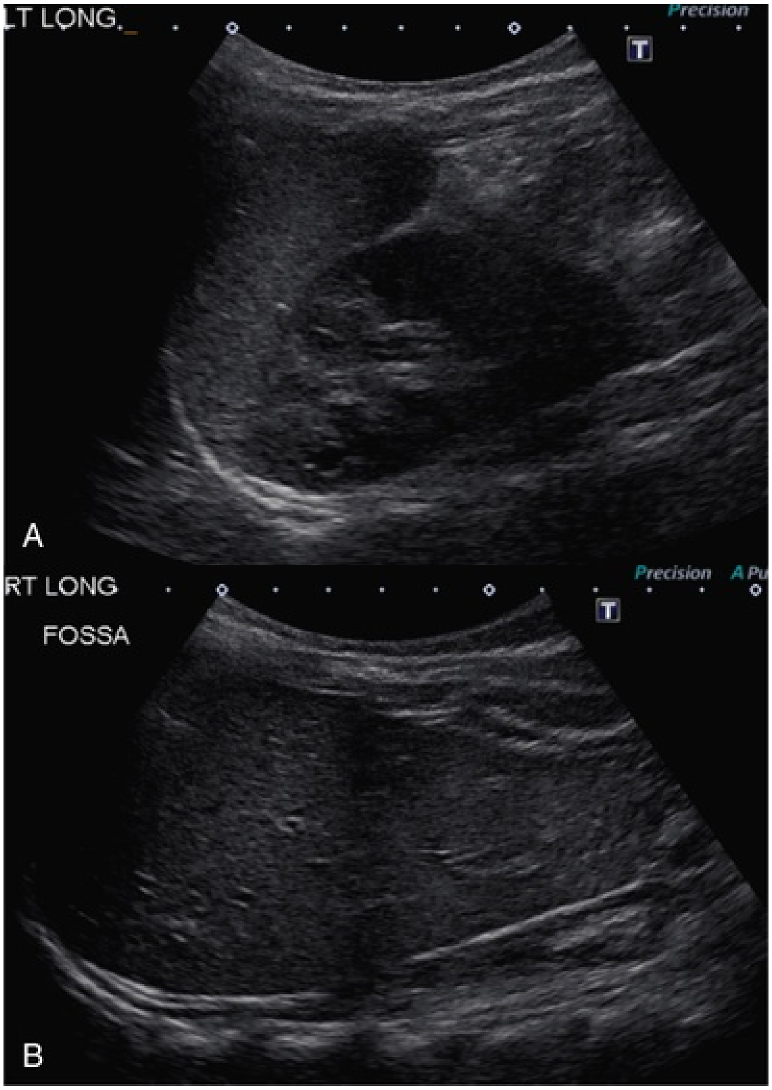
Although the contralateral kidney is usually morphologically normal, it may be associated with a number of congenital defects such as agenesis, ectopia, or vesicoureteral reflux (Malek et al., 1971; Thompson and Pace, 1937; Chow et al., 2005). As mentioned earlier, bilateral renal ectopia occurs infrequently (10%), **and the adrenal gland is not expected to be absent or abnormally positioned as renal ascent does not influence adrenal gland development.**

Renal ectopia has a strong association with reproductive structure anomalies, and the incidence varies from 15% (Thompson and Pace, 1937) **to 45%** (Downs et al., 1973). Twenty percent to 66% of females have one or more of the following abnormalities of the reproductive organs: bicornuate or unicornuate uterus with atresia of one horn, rudimentary or absent uterus and proximal and/or distal vagina, and duplication of the vagina (D'Alberton et al., 1981; Hall-Craggs et al., 2013; McCrea, 1942; Donahoe and Hendren, 1980). Among male patients, Guarino et al. reported an incidence of hypospadias and undescended testicle of 5% for each condition in their series of 60 boys with renal ectopia (Guarino et al., 2004). Others have reported 10% to 20% rates of recognizable associated genital defect; undescended testes; duplication of the urethra; and hypospadias (Thompson and Pace, 1937).

Anomalies of other organ systems have been described in patients with ectopic kidneys (Dogan et al., 2017; Downs et al., 1973); most involve the skeletal or cardiac systems. Fourteen percent of patients with a cloacal malformation have an ectopic kidney (Dursun et al., 2005).

Diagnosis

As imaging modalities have become more widespread in their usage, ectopic kidneys are diagnosed and discovered more frequently. Prenatal ultrasonography can detect ectopic kidneys in a variety of locations such as the pelvis or thorax (Chow et al., 2005; Meizner et al., 1995). The diagnosis of an ectopic lumbar or pelvic kidney is made when whatever renal imaging modality fails to show a kidney in its orthotopic location, and reniform tissue is identified in the lower abdomen or pelvis (Fig. 38.8). **Most ectopic kidneys are asymptomatic.** However, the ectopic kidney can produce a variety of symptoms such as vague abdominal pain, renal colic secondary to an obstruction, or hematuria (Gleason et al., 1994; Livermore and Thiruchelvam, 2010). Renal ectopia may also present with a urinary tract infection (UTI) or a palpable abdominal mass (Karmi, 1977; Gleason et al., 1994). Continuous urinary incontinence in females with normal voiding habits should prompt an evaluation for ectopic ureter. In such a clinical scenario when the initial evaluation yields the diagnosis of a solitary kidney, the potential for renal ectopia with an ectopically draining ureter may exist (Borer et al., 1998). Diagnosis may be difficult because of the diminished function of some ectopic kidneys. An ectopic kidney may be very small and/or dysplastic with essentially no function, leading to the misdiagnosis of URA. DMSA scanning and/or MRU may be necessary to diagnose in such cases (see Fig. 38.8). Cystoscopy, when performed, usually will reveal ureteral orifices that are invariably normal unless the ureteral orifice is also ectopic.



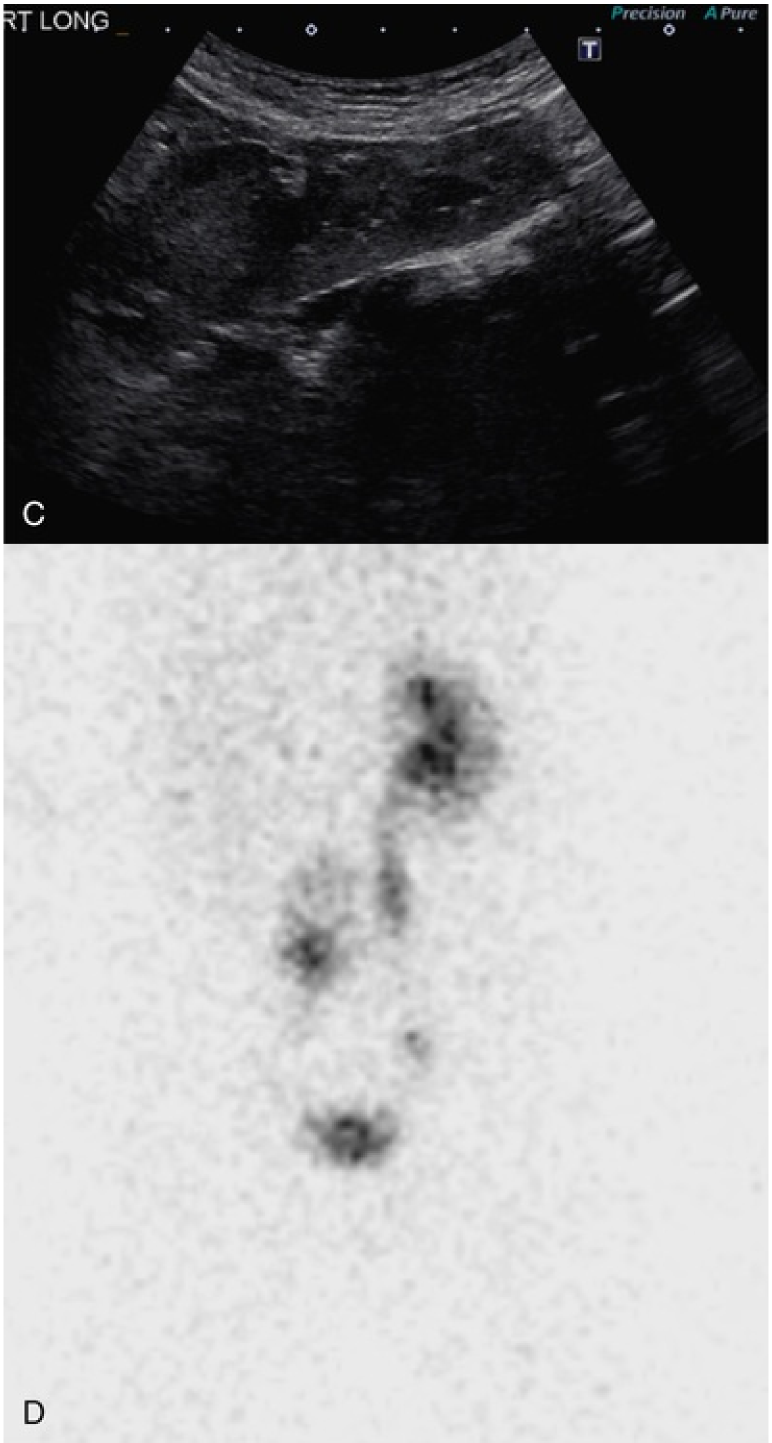


FIG. 38.8 Three-month-old patient with a history of prenatal abnormal renal ultrasound. (A) Sonogram of left orthotopic kidney. (B) Sonogram of right empty renal fossa. (C) Sonogram of right pelvic ectopic kidney. (D) DMSA renal scan of ectopic pelvic kidney revealed 27% differential function relative to 73% of its contralateral orthotopic mate.

Prognosis

The ectopic kidney is no more susceptible to disease than the orthotopic kidney, except for the development of hydronephrosis or stones (Gleason et al., 1994; Benchekroun et al., 2002). This may be a result of the anteriorly placed pelvis and malrotation of the kidney, which may impair drainage of urine from a high insertion of the ureter to the pelvis or anomalous vasculature that partially obstructs one of the major calyces or the upper ureter. In addition, there may be an increased risk for injury from blunt abdominal trauma, because the low-lying kidney is not protected by the rib cage. Van den Bosch et al. examined the urologic and nephrologic consequences of both simple and crossed renal ectopia (Van den Bosch et al., 2010). They found no adverse effects on blood pressure or kidney function during childhood. Many studies have reported that global renal function can be normal in patients with unilateral renal ectopia, however the relative function of the ectopic kidney on DMSA scan may demonstrate decreased function in most instances (Van den Bosch et al., 2010; Guarino et al., 2004; Dogan et al., 2017) (see Fig. 38.8). Pregnant women with renal ectopia found no increased occurrence of maternal or fetal complications related to the ectopic kidney (Anderson and Harrison, 1965; Delson, 1975). Dystocia from a pelvic kidney is rare but may require cesarean section (Freilich and Brint, 1957; Mckenzie, 1950). Before modern imaging, instances have occurred in which solitary ectopic kidneys were mistaken for pelvic malignancies and were removed (Downs et al., 1973).

Cephalad Renal Ectopia

The kidney may be positioned more craniad than normal in a subdiaphragmatic position resulting in cephalad renal ectopia. This can occur when there is an omphalocele and the liver herniates into the omphalocele with the intestines, allowing the kidneys to continue ascension until the diaphragm arrests their ascent (Pinckney et al., 1978). The kidneys are positioned immediately beneath the diaphragm near the level of the 10th thoracic vertebra. The ureters are longer than normal but otherwise normal. A color Doppler sonogram or MR arteriography demonstrates that the origin of each renal artery is more cephalad than normal (Fig. 38.9). Patients usually have no symptoms caused by malposition, and urinary drainage is not impaired. Cephalad renal ectopia has also been described when abdominal wall defects are absent (Kaur and Chawla, 1980; Kundu and Goswami, 1995; Bulgrin and Hokmes, 1955; Baurys and

Servoss, 1949; Zolotas and Krishnan, 2016). Zolotas and Krishnan reported on male infants with a series of antenatal and the first postnatal ultrasound scans demonstrating the right kidney located within the right renal fossa (Zolotas and Krishnan, 2016). On subsequent follow-up imaging during the first 3 months of life, the kidney migrated to a subdiaphragmatic position, which was confirmed on MRI scan (see Fig. 38.9).

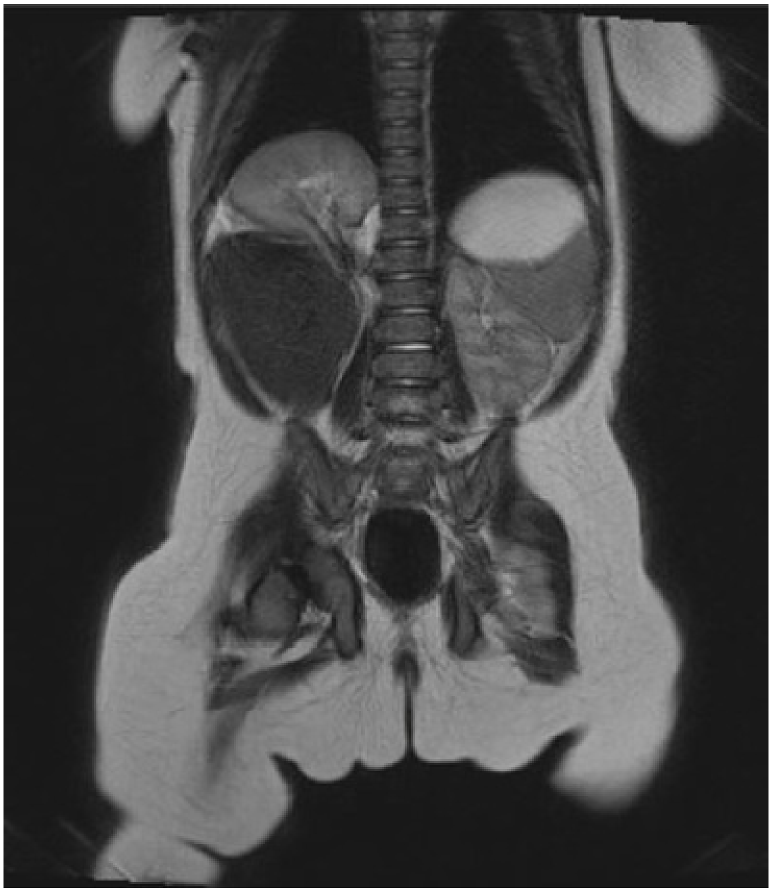

FIG. 38.9 Magnetic resonance image of the coronal view of the abdomen and chest in 4-month-old patient with a history of right ectopic kidney. The right kidney appears in a subdiaphragmatic position. (From Zolotas E, Krishnan RG. Subdiaphragmatic renal ectopia: case report and review of the literature. *Case Rep Nephrol*. 2016;2016:1084917.)

Thoracic Kidney

Intrathoracic ectopia denotes either a partial or a complete protrusion of the kidney above the level of the diaphragm into the posterior mediastinum.

Incidence

This is a rare anomaly, with less than 5% of patients with renal ectopia having an intrathoracic kidney and an estimated incidence of 1 : 13,000 at autopsy (Campbell, 1930). Several case reports of patients with a thoracic kidney have been reported (Lacasta Garcia et al., 1999). Bilateral ectopic thoracic kidneys have also been described (Dingeldein et al., 2008; Liddell et al, 1989). There appears to be a slight left-sided predominance of 1.5 : 1, and the sex ratio favors males by 2 : 1 (Lozano and Rodriguez, 1975). This entity has been found on prenatal ultrasonography (Masturzo et al., 2001) and in all age groups, however, it is more commonly detected in adults undergoing chest radiography for other reasons (Drop et al., 2003).

Embryology

When the kidney reaches its typical location by the end of 8 weeks' gestation, the diaphragmatic leaflets are formed as the pleuroperitoneal membrane, which separates the pleural from the peritoneal cavity. Mesenchymal tissues associated with this membrane eventually form the muscular component of the diaphragm. Two possibilities exist for the occurrence of an ectopic intrathoracic kidney: either delayed closure of the diaphragmatic anlage allows for protracted renal ascent above the level of the future diaphragm or, alternatively, the kidney overshoots its usual position because of accelerated ascent before normal diaphragmatic closure (N'Guessan and Stephens, 1984). Delayed involution of mesonephric tissue has been proposed as the most likely causative factor (Angulo et al., 1992) because intrathoracic kidneys occur in only 0.25% of patients with a diaphragmatic hernia (Donat and Donat, 1988). Renal angiography has demonstrated either a normal site (Lundius, 1975) or a more cranial origin (Franciskovic and Martincic, 1959) of the renal artery from the aorta supplying the thoracic kidney (Fig. 38.10).

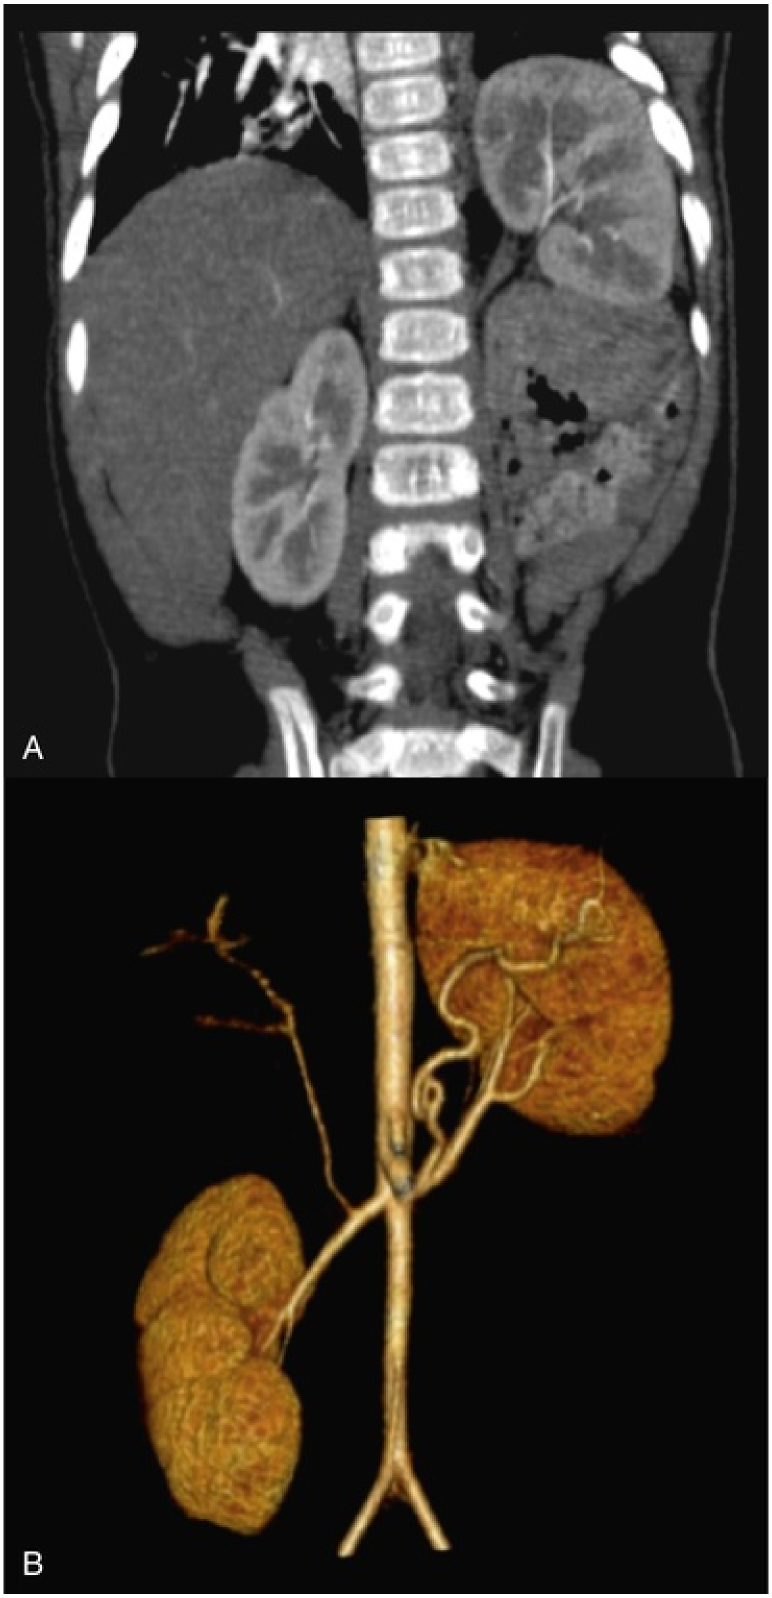

FIG. 38.10 One-year-old female with multiple congenital anomalies including cardiac anomalies. (A) Computed tomography (CT) coronal views after administration of intravenous contrast revealing left intrathoracic

kidney. (B) Three-dimensional CT reconstruction of renal arterial vasculature.

Description

The kidney is situated in the posterior mediastinum and usually has completed the normal rotation process. The renal contour and collecting system are normal. Thoracic kidney has been described in four basic categories: (1) true ectopia; (2) diaphragm eventration; (3) diaphragmatic hernia; and (4) traumatic diaphragm injuries (Donat and Donat, 1988). The kidney usually lies in the posterolateral aspect of the diaphragm in the foramen of Bochdalek. At this point, the diaphragm thins out and a flimsy membrane surrounds the protruding portion of kidney. Therefore the kidney is not within the pleural space (N'Guessan and Stephens, 1984). The lower lobe of the adjacent lung may be hypoplastic secondary to compression by the kidney mass. The renal vasculature and the ureter enter and exit from the pleural cavity through the foramen of Bochdalek.

Associated Anomalies

The ureter is elongated to accommodate the excessive distance to the bladder (N'Guessan and Stephens, 1984). The adrenal gland typically occupies its normal location, and the contralateral kidney is usually normal. However, cases of ectopic adrenal glands in association with thoracic kidneys have been described (Dingeldein et al., 2008; Donat and Donat, 1988). No consistent anomalies have been described in other organ systems.

Symptoms

The vast majority of affected individuals are asymptomatic. Flank pain was the presenting symptom in a case of UPJ obstruction in a thoracic kidney (Hampton and Borden, 2002). Respiratory symptoms have led to the diagnosis of intrathoracic kidney (Langer et al., 2015; Maduekwe et al., 2011). Renal function is typically normal with an ectopic intrathoracic kidney.

Diagnosis

The diagnosis is commonly made after a routine chest radiograph shows the affected hemidiaphragm slightly elevated. A smooth, rounded mass is seen extending into the chest near the midline on an anteroposterior radiograph and along the posterior aspect of the diaphragmatic leaflet on a lateral view. A thoracic kidney may be found at the time of thoracotomy for a suspected mediastinal tumor (DeNoronha et al., 1974). CT or MRU is currently the imaging modality of choice (see Fig. 38.10).

Prognosis

Neither autopsy series nor clinical reports suggest that a thoracic kidney will inevitably lead to serious urinary or pulmonary complications. Therefore surgical intervention is reserved for clinical signs and/or symptoms.

Key Points: Anomalies of Renal Ascent

- The left side is affected slightly more than the right.
- Hydronephrosis is a common finding in ectopic kidneys, with etiology resulting from obstruction at the ureteropelvic or ureterovesical junction, high-grade vesicoureteral reflux, or the malrotation alone.
- Vesicoureteral reflux has been found in 30% to 50% of children with ectopic kidneys, either into the ectopic kidney or the contralateral side.
- The incidence of genital anomalies in the patient with ectopia is about 15%.
- The majority of ectopic kidneys are clinically asymptomatic.
- Differential renal function of the ectopic kidney may show decreased function on nuclear scan.

Anomalies of Renal Form and Fusion

Crossed Renal Ectopia With and Without Fusion

When a kidney is located on the side opposite that in which its ureter inserts into the bladder, the condition is known as *crossed renal ectopia*. **Ninety percent of crossed ectopic kidneys are fused to their ipsilateral mate.** Crossed renal ectopia accounts for the second most common renal fusion anomaly after horseshoe kidney. Renal fusion anomalies are usually diagnosed in children as part of a constellation of malformations, in young adults during evaluation for delayed menarche, and in the elderly as incidental findings (Glodny et al., 2008). **McDonald and McClellan in 1957 proposed the categorization of crossed renal ectopia into four groups: crossed ectopia with fusion, crossed ectopia without fusion, solitary crossed ectopia, and bilaterally crossed ectopia** (McDonald and McClellan, 1957) **(Fig. 38.11).** When crossed renal ectopia with fusion occurs, the fusion anomalies are designated as (1) unilateral fused kidney with inferior ectopia; (2) sigmoid, or *S*-shaped; (3) lump, or cake; (4) *L*-shaped, or tandem; (5) disc, shield, or doughnut; and (6) unilateral fused kidneys with superior ectopia (Fig. 38.12).

Incidence

Abeshouse and Bhisitkul (1959) reported almost 500 cases of crossed ectopia with and without fusion that presented primarily with clinical symptoms. Glodny et al. reported on 24 crossed fused ectopia found on CT scan performed for non-neurologic indications (Glodny et al., 2008). **Cases of crossed renal ectopia without fusion have been reported** (Ramaema et al., 2012; Pelegrí Gabarró et al., 2014; Felzenberg and Nasrallah, 1991). It is estimated that crossed nonfused renal ectopia represents approximately 10% of all crossed ectopic kidneys (Lee, 1949; Abeshouse and Bhisitkul, 1959). The anomaly occurs more commonly in males with a ratio of 2 : 1, and left-to-right ectopia is seen three times more frequently than right-to-left ectopia (Lee, 1949). **Solitary crossed ectopia has been reported** (Miles et al., 1985; Gu and Alton, 1991; Livermore and Thiruchelvam, 2010). Males predominate with a ratio of 2 : 1. The crossed ectopia involves migration of the left kidney to the right side with absence of the right kidney, rather than the reverse, with a ratio of almost 2 : 1 (Kakei et al., 1976). In most cases, the kidney fails to ascend to an orthotopic location and rotate completely. Bilateral crossed renal ectopia has been described (Abeshouse and Bhisitkul, 1959) and is considered the rarest form.

Abeshouse and Bhisitkul (1959) compiled 443 reports of crossed ectopia with fusion and estimated its occurrence at 1 in 1000 live births. This figure varies with the type of fusion anomaly; **the unilaterally fused kidney with inferior ectopia is the most common variety, whereas fusion with superior ectopia is the least common.** The autopsy incidence has been calculated at 1 in 2000 (Baggenstoss, 1951). There is a slight male predominance (3 : 2). As in renal ectopia without fusion, renal ectopia with fusion has a predilection for left-to-right crossover compared with the contrary.

Embryology

As mentioned earlier, the mechanisms responsible for complete ascent of the kidney remain unknown, and therefore **the cause of crossed ectopia is also unknown.** Several authors have proposed different theories to its development. Cook and Stephens postulated that crossover is the result of malalignment and abnormal rotation of the caudal end of the developing fetus, with the distal curled end of the vertebral column being displaced to one side or the other (Cook and Stephens, 1977). As a result, either the cloaca and WD structures lie to one side of the vertebral column, allowing one ureter to cross the midline and enter the opposite nephrogenic blastema, or the kidney and ureter are transplanted to the opposite side of the midline during "normal" renal ascent (Hertz et al., 1977; Maizels and Stephens, 1979). Some have implicated teratogenic factors given observed incidence of associated genitourinary and other organ system anomalies in one series (Kelalis et al., 1973). Finally, genetic influences may play a role, because familial inheritance of crossed renal ectopia has been reported (Rinat et al., 2001). **Fusion of the metanephric masses can occur in the true pelvis before or at the start of cephalad migration, or it may occur during the latter stages of ascent.** The extent of fusion is determined by the proximity of the developing renal anlagen to one another. After fusion, midline retroperitoneal structures, the aortic bifurcation, the inferior mesenteric artery, and the base of the small bowel mesentery may impede advancement of the kidneys toward their normal location.

Description

Fusion of a crossed ectopic kidney is related to the time it comes in contact with its mate. The crossed kidney usually lies caudad to its normal counterpart on that side. Based on clinical observation and reported frequencies, it is likely that migration of each kidney begins simultaneously, but ascent of the ectopic renal unit lags behind because of crossover time. **Therefore the superior pole of the crossed ectopic kidney usually joins with the inferior aspect of the normal kidney. Ascent continues either until the uncrossed kidney reaches its normal location or until one of the retroperitoneal structures prevents further migration of the fused kidneys. The final shape of the crossed fused ectopic kidney depends on the time, extent of fusion, and the degree of renal rotation that has occurred.** No further rotation is likely after the two kidneys have joined. Orientation of the renal pelvis can provide further insight into the timing of the fusion anomaly. An anteriorly placed pelvis suggests early fusion, whereas a medially positioned renal pelvis indicates that fusion probably occurred after rotation was completed.

When crossed renal ectopia occurs without fusion, the uncrossed kidney usually resides in its orthotopic location with proper orientation, whereas the ectopic kidney is inferior and is in either a diagonal or a horizontal position with an anteriorly placed renal pelvis. A variable distance usually separates the two kidneys, each with its own capsule of Gerota fascia surrounding it. In every case of crossed ectopia without fusion, the ureter from the normal kidney enters the bladder on the same side, and that of the ectopic kidney crosses the midline at the pelvic brim and enters the bladder on the contralateral side (Fig. 38.13). In cases of solitary crossed ectopia, the kidney is usually located somewhat low but in the opposite renal fossa at the level of L1 to L3 and is oriented anteriorly, having incompletely rotated on its vertical axis (Miles et al., 1985; Purpon, 1963). When the kidney remains in the pelvis or ascends only to the lower lumbar region, it may assume a horizontal lie with an anteriorly placed pelvis because it has failed to rotate fully (Trabrisky and Bhisitkul, 1965). The ureter crosses the midline above the S2 vertebra and enters the bladder on the opposite side (Gu and Alton, 1991; Livermore and Thiruchelvam, 2010) (see Fig. 38.13). The contralateral ureter, if present, is often rudimentary (Caine, 1956). Bilateral crossed ectopia may have normal-appearing kidneys and renal pelves, but the ureters cross the midline at the level of the lower lumbar vertebrae (Abeshouse and Bhisitkul, 1959).

Inferior Ectopic Kidney

Two-thirds of all unilaterally fused kidneys involve inferior ectopia. Both renal pelves are anterior, so fusion probably occurs relatively early (Fig. 38.14).

Sigmoid, or *S*-Shaped, Kidney

The sigmoid, or *S*-shaped, kidney is the second most common anomaly of fusion. The crossed kidney is inferior, with the two kidneys fused at their adjacent poles (see Fig. 38.12). Fusion of the two kidneys occurs relatively late, after complete rotation on the vertical axis has occurred. Therefore, each renal pelvis is oriented correctly, and they face in directions opposite from one another. The lower convex border of one kidney is directly opposite the outer border of its counterpart, creating an *S*-shaped appearance to the entire renal outline. The ureter from the normal kidney courses downward anterior to the outer border of the inferior kidney, and the ectopic kidney's ureter crosses the midline before entering the bladder.

Cake, or Lump, Kidney

The cake, or lump, kidney is a relatively rare form of fusion (Glenn, 1958) (Fig. 38.15). The total kidney is irregular and lobulated, which is contradistinct to the disc kidney (see Fig. 38.12). Ascent usually progresses only as far as the sacral promontory, but in many instances the kidney remains within the true pelvis. Anomalies of the ureteral anatomy have been reported as well; specifically solitary ureter draining both moieties (Brock et al., 1983; Goren and Eidelman, 1987; Calado et al., 2004). Reproductive malformations such as unicornuate uterus and bilateral absence of the vas have been described in association with cake kidney in both males and females (Schwartz et al., 2010; Rosenkrantz et al., 2010).

the anterior blood supply coming from above and the ureters leaving from below. (B) Sonogram of cake kidney in sagittal view *(arrows)*. (A, Courtesy of Dr. H.S. Altman. B, Courtesy Dr. Shpetim Telegrafi.)

L-Shaped Kidney

The *L*-shaped, or tandem, kidney occurs when the crossed kidney assumes a transverse position at the time of its attachment to the inferior pole of the normal kidney (see Fig. 38.12). The crossed kidney lies in the midline or in the contralateral paramedian space anterior to the L4 vertebra. Rotation about the long axis of the kidney produces an inverted or a reversed pelvic position. The ureter from each kidney enters the bladder on its respective side (Iwanaga et al., 2018).

Disc Kidney

The disc kidney is known by several other names such as pancake, shield, or doughnut kidney. One of the earliest published reports of this fusion type was by Looney and Dodd; however others have reported it (Looney and Dodd, 1926; Tiwari et al., 2014). It can be described as a renal mass located in the pelvis, which is formed by complete medial fusion of renal parenchyma without intervening septum creating a disc, or shield, shape (see Fig. 38.12). The lateral aspect of each kidney retains its normal contour. This type of fusion differs from the lump, or cake, kidney in that the reniform shape is better preserved because there is a less extensive degree of fusion. Each kidney has its own collecting system and anteriorly oriented ureters that enter the bladder normally. However, there are case reports from autopsies of pancake kidney with two major calyces joined to form a single renal pelvis from both kidneys, which join and continue as a single ureter (Horai et al., 2018; Kanchan et al., 2017; Ghawanmeh et al., 2017).

Superior Ectopic Kidney

The least common variety of renal fusion is the crossed ectopic kidney that lies superior to the normal kidney. The lower pole of the crossed kidney is fused to the upper pole of the normal kidney (see Fig. 38.12). The renal units retain a fetal orientation, with both pelves lying anteriorly, suggesting that fusion occurred very early (Akdogan et al., 2015; Yin et al., 2014).

Regardless of the type of fusion encountered, the vascular supply to the kidneys is variable. The crossed ectopic kidney is supplied by one or more branches from the aorta or common iliac artery (Rubinstein et al., 1976; Glodny et al., 2008). The normal kidney frequently has an anomalous blood supply, with multiple renal arteries originating from various levels along the aorta. The solitary crossed ectopic kidney generally receives its blood supply from the aorta or iliac artery on the side where it is positioned (Tanenbaum et al., 1970).

Associated Anomalies

In all the types of fusion anomalies, the ureteral orifice associated with each kidney is usually orthotopic. Most patients with crossed ectopia have a normal trigone, however the incidence of an ectopic ureteral orifice from the crossed renal unit is about 3% (Abeshouse and Bhisitkul, 1959; Hendren et al., 1976). The ureter from the uncrossed renal segment of a fusion anomaly occasionally has an ectopic orifice or an associated ureterocele (Mishra and Kapoor, 1995; Fishman and Borden, 1982; Hendren et al., 1976). Vesicoureteral reflux is noted in 20% of crossed ectopia and in 71% of bilateral crossed ectopia (Kelalis et al., 1973; Guarino et al., 2004) (Fig. 38.16). Currarino and Weisbruch reported 10 cases of midline renal fusion in which a single ureter divided into two pelves that stretched across the midline to drain one respective half of the total parenchymatous mass (Currarino and Weisbruch, 1989). In 4 of the 10 cases, a second ureter was present that drained a separate duplex system on either the right or left side. Most of the affected individuals had an imperforate anus, an abnormal vertebra, or both.

Several cases of renal tumors have been reported in kidney fusion anomalies of varying histology (Stimac et al., 2004; Grotas and Phillips, 2009; Lee, 1949; Redman and Berry, 1977; Rac et al., 2016; Walther et al., 2013; Gur et al., 2003). Anomalies of the skeletal system and genital organs have been reported in patients with solitary renal ectopia (Gleason et al., 1994). **Genital anomalies described in either renal ectopia with or without fusion are: cryptorchidism, hypospadias, absence of the vas deferens, absence of testicle, vaginal atresia, and a unilateral uterine abnormality** (Drevna et al., 2018; Kakei et al., 1976; Kelalis et al., 1973). Imperforate anus has also been observed in 20% of those with solitary crossed ectopia. In general, the occurrence of an associated nonurologic anomaly in crossed renal ectopia, excluding solitary crossed ectopia, is low; the most frequent are imperforate anus (4%), orthopedic anomalies (4%), skeletal abnormalities, and cardiovascular septal defects.

Symptoms

Most individuals with crossed ectopic anomalies present no symptoms. These anomalies are often discovered incidentally at autopsy, during routine perinatal ultrasound, or during imaging for another clinical indication. When symptoms occur, they usually develop in the third or fourth decade of life, and they include vague lower abdominal pain, pyuria, hematuria, and UTI (Gleason et al., 1994). It is believed that the abnormal kidney position and the anomalous blood supply may impede drainage from the collecting system, creating a predisposition to UTI and calculus formation (Collura et al., 2004) (Fig. 38.16). Romans et al. observed that when a stone in a crossed ureter causes colic, the pain is lateralized to the anephric side or the side of the embryonic origin of the ureter, whereas when there is pyelonephritis or obstruction at the UPJ in the crossed kidney, the lumbar pain is on the side of the kidneys (Romans et al., 1976). These observations suggest ureteral, not renal, migration as a causative factor in crossed ectopia. **An asymptomatic abdominal mass is the presenting sign in one-third of cases** (Abeshouse and Bhisitkul, 1959; Nussbaum et al., 1987; Karmi, 1977). Hypertension evaluation may uncover an ectopic fusion anomaly (Akdogan et al., 2015).

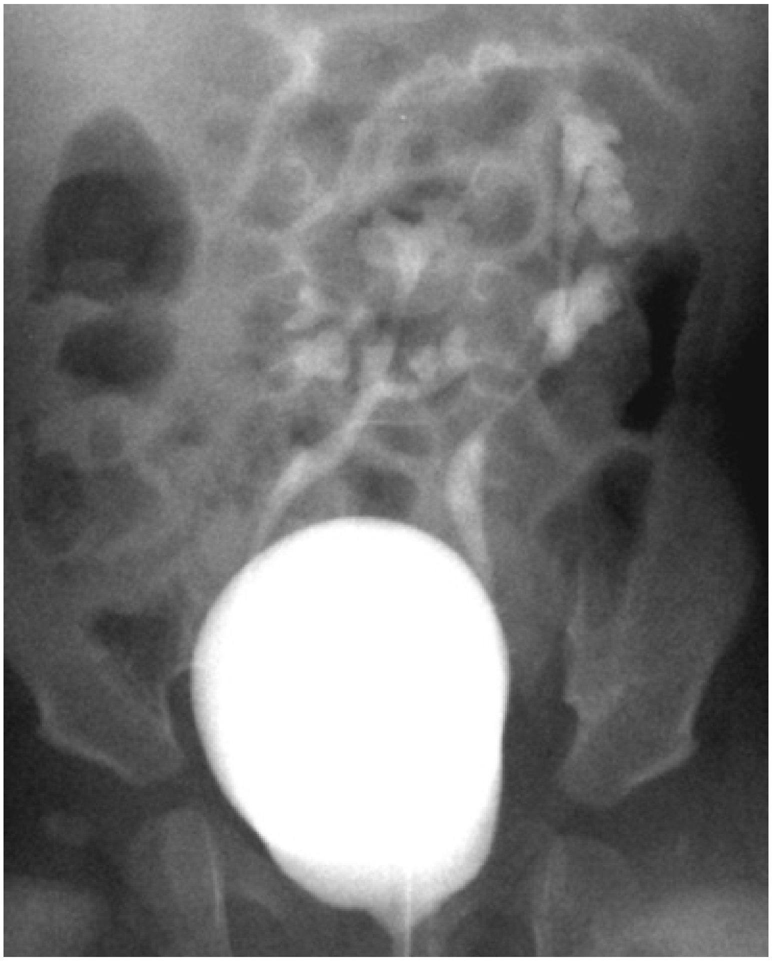

FIG. 38.16 Voiding cystogram demonstrated bilateral grade 3 vesicoureteral reflux into a right-to-left crossed fused renal system.

Diagnosis

Ultrasonography is frequently used to diagnose renal fusion abnormalities in the pediatric population given the higher utilization in this age group compared with adults (Glodny et al., 2008). Indications for pediatric renal imaging may be for screening purposes when syndromic conditions associated with renal anomalies are diagnosed. Nuclear scans can be utilized to identify functioning renal tissue, and diuretic components can assist in determining drainage patterns of associated collecting systems (Volkan et al., 2003; Gambhir et al., 2015). Multidetector three-dimensional CT urography is excellent for delineating the renal parenchyma, collecting system, ureters, and vascular supply of the kidneys whatever the fusion anomaly may be (Türkvatan et al., 2006; Pupca et al., 2014). The main limitation of CT is the increased risk for significant radiation exposure, which is especially problematic for children, pregnant women, and individuals requiring repeat examinations (Türkvatan et al., 2009). MRU and magnetic resonance arteriography (MRA) should be performed in children undergoing extensive surgery on an ectopic kidney to obtain more information while minimizing radiation exposure. Cystoscopy and retrograde pyelography can be useful in mapping the collecting system and pattern of drainage when MRU does not provide sufficient anatomic detail.

Prognosis

Most individuals with crossed renal ectopia have normal longevity. However, those with an obstructive-appearing collecting system are at risk for development of UTI, renal calculi, or both. As is the case with renal cancers in orthotopic kidneys, the prognosis of patients with renal malignancies in cases of renal ectopia is related to the stage and histology of the tumor (Dhillon et al., 2014).

Key Points: Crossed Renal Ectopia With and Without Fusion

- When a kidney is located on the side opposite that in which its ureter inserts into the bladder, the condition is known as crossed ectopia.
- Ninety percent of crossed ectopic kidneys are fused with their mate; the superior pole of the ectopic kidney usually joins with the inferior aspect of the normal kidney.

Horseshoe Kidney

The horseshoe kidney is the most common of all renal fusion anomalies. The anomaly consists of two distinct renal masses lying vertically on either side of the midline and connected at their respective lower poles by a parenchymatous or fibrous isthmus that crosses the midplane of the body (Natsis et al., 2014).

Incidence

Horseshoe kidney occurs in 0.25% of the population, or about 1 in 400 individuals (Campbell, 1970). Reported incidence based on radiographic imaging has shown similar results: between 1 in 474 and 1 in 666 individuals (Weizer et al., 2003; Glodny et al., 2009). Horseshoe kidney is found more commonly in males with a ratio slightly greater than 2 : 1 (Weizer et al., 2003; Glodny et al., 2009). Horseshoe kidneys have been reported in identical twins (Bridge, 1960) and among several siblings (David, 1974). It is doubtful that this anomaly represents a particular genetic predisposition, but it may be the result of a genetic expression with a low degree of penetrance (Leiter, 1972). The abnormality has been discovered in multiple congenital anomalies associated with the horseshoe kidney, some of which are incompatible with long-term survival (Scott, 2002).

Description

In 95% of cases, the kidneys join at the lower pole, which occurs before the kidneys have rotated on their long axes. There may or may not be symmetry to the size of each moiety (Glodny et al., 2009). In one study examining 90 horseshoe kidneys, 36 kidneys had midline fusions (40%), 34 had left lateral fusions (38%), and 20 had right lateral fusions (22%). The pelves and ureters of the horseshoe kidney are usually anteriorly placed, crossing ventrally to the isthmus. Very rarely, the pelves are anteromedial, suggesting that fusion occurred after some rotation occurred. **In a small subset, an isthmus connects both upper poles** (Love and Wasserman, 1975). In addition, cephalad migration is usually incomplete, and it is thought that the inferior mesenteric artery prevents full ascent.

The isthmus is generally bulky and consists of parenchymatous tissue with its own blood supply (Glenn, 1959; Love and Wasserman, 1975). Occasionally it is just a flimsy midline structure composed of fibrous tissue that tends to draw the renal masses close together. The isthmus is located adjacent to the L3 or L4 vertebra just below the origin of the inferior mesenteric artery from the aorta. The isthmus most often lies anterior to the aorta and vena cava, but it has been reported to pass between the inferior vena cava and the aorta or even behind both great vessels (Dajani, 1966). In some instances, the anomalous kidneys are very low, anterior to the sacral promontory or even in the true pelvis behind the bladder (Campbell, 1970).

The calyces are normal in number and are atypical in orientation. Because the kidney fails to rotate, the calyces point posteriorly, and the axis of each pelvis remains in the vertical or obliquely lateral plane (on a line drawn from the lower to the upper poles). The lowermost calyces extend caudally or even medially to drain the isthmus and may overlie the vertebral column (Strauss et al., 2000). The ureter may insert high on the renal pelvis and lie laterally, probably as the result of incomplete renal rotation. It courses downward and has a characteristic bend as it crosses over and anterior to the isthmus (Strauss et al., 2000). The lower ureter enters the bladder normally, however there have been several cases of atypical ureteral course and anatomy such as retrocaval ureter, ureteral ectopia, and duplication (Khong et al., 1996; Knutson and Hawas, 2004; Tyagi et al., 2014; Keskin et al., 2009).

The blood supply to the horseshoe kidney can be variable, and a single artery and vein to each moiety is the exception rather than the norm. CT imaging studies of 90 patients with horseshoe kidneys revealed a highly variable pattern of arterial and renal vasculature related to number (Glodny et al., 2009)**. In the Glodny et al. study, only 5% of the patients had the simple situation of only one artery on each side, whereas others have reported between 20% to 30% of cases with one renal artery to each kidney** (Glodny et al., 2009; Glenn, 1959; Crawford et al., 1988). The blood supply to the isthmus and lower poles is also variable. The isthmus and adjacent parenchymal masses might receive a branch from each main renal artery, or they may have their own arterial supply from the aorta originating either above or below the level of the isthmus. There is tremendous variability to the origin of renal vasculature to a horseshoe kidney. Not infrequently, branches from the inferior mesenteric, common or external iliac, or sacral arteries supply this area (Kolln et al., 1972; Crawford et al., 1988; Glodny et al., 2009).

Associated Anomalies

There are many congenital anomalies and syndromes associated with horseshoe kidney. Je et al. examined their institution's experience over a 24-year period with 366 children and young adults and 14 fetuses with horseshoe kidney (Je et al., 2015). One-half of the subjects had extrarenal diseases or syndromes, and gastrointestinal and vertebral anomalies were the most common. The autopsy incidence of other anomalies is greater in children who die at birth or in early infancy than in those who reach adulthood (Scott, 2002). This implies that a horseshoe kidney occurs more often in association with other serious congenital anomalies. Horseshoe kidney is found in 3% of children with neural tube defects (Whitaker and Hunt, 1987). Anorectal malformations are frequently encountered in these patients as part of the VATER (vertebral, anorectal, tracheoesophageal fistula, renal) anomalies syndrome. Horseshoe kidney is seen in 60% of females with Turner syndrome (Lippe et al., 1988). In the study by Je et al., 13% of the patients had syndromes, with Turner syndrome the most common followed by caudal regression syndrome (Je et al., 2005).

Genitourinary anomalies can be associated with a horseshoe kidney (Je et al., 2005; Boatman et al., 1972). Hypospadias and undescended testes occurred in 4% of the males, and a bicornuate uterus, a septate vagina, or both were noted in 7% of the females. Vesicoureteral reflux has been noted in 8% to 32% of patients with horseshoe kidney (Cascio et al., 2002; Pitts and Muecke, 1975; Segura et al., 1972; Wilson and Azmy, 1986). Management of vesicoureteral reflux in children with horseshoe kidney is no different than in children with normal kidneys. Cascio et al. observed that of the 20 refluxing ureters, 15 spontaneously resolved and 5 needed surgical intervention to correct reflux. Hydronephrosis is not an uncommon radiographic finding with horseshoe kidneys. This can be secondary to nonrefluxing and nonobstructing etiology. Hydronephrosis secondary to UPJ obstruction ranges from 13% to 34% in previously published clinical series (Fig. 38.17) (Whitehouse, 1975; Das and Amar, 1984; Pitts and Muecke, 1975; Segura et al, 1972; Wilson and Azmy, 1986). The UPJ obstruction can be caused by a variety of factors. High insertion of the ureter into the renal pelvis, its abnormal course anterior to the isthmus, and extrinsic compression from the anomalous blood supply to the kidney may individually or collectively contribute to the hydronephrosis.

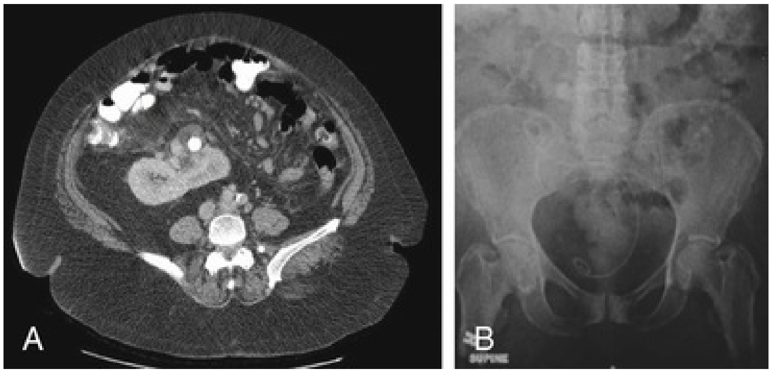

FIG. 38.17 A 42-year-old female presented with abdominal pain and emesis. (A) Computed tomography scan of abdomen and pelvis reveals obstructing stone in left-to-right crossed fused ectopic kidney. (B) Postprocedure abdominal radiograph shows internal ureteral stent within the left crossed ectopic kidney. Note the stent exiting the left ureteral orifice and crossing midline into the renal pelvis located in the right lower quadrant.

In the modern era, horseshoe kidneys are frequently discovered incidentally, and their apparent hydronephrosis more often shows a nonobstructed pattern on radionuclide scanning. Horseshoe kidneys can be incidentally observed on ^{99m}Tc bone scan as a result of renal uptake and excretion of the isotope (O'Brien et al., 2008). Cystic disease, including multicystic dysplasia in one-half (the upper pole) of one side (Boullier et al., 1992) and adult polycystic kidney disease have been reported with horseshoe kidney (Correa and Paton, 1976). DMSA scanning in 22 patients showed asymmetrical function between the two moieties of horseshoe kidney in 63% (Kao et al., 2003).

Stone formation has been commonly seen in horseshoe kidney. In a meta-analysis, Pawar et al. observed that kidney stones are very common in adult patients with horseshoe kidney, with an estimated incidence of 36% (Pawar et al., 2018). Calcium-based stones are the most prevalent kidney stones in adults with horseshoe kidney. Metabolic stone evaluation in 11 of 37 of stone formers with horseshoe kidneys showed at least one abnormality, with an average of 2.68 abnormalities per 24-hour urine collection. Hypovolemia, hypercalciuria, and hypocitraturia were the most common metabolic defects (Raj et al., 2004). The number and types of abnormalities appear similar to those observed in stone formers without horseshoe kidneys.

Symptoms

At least 50% with horseshoe kidneys are asymptomatic, and in most instances the anomaly is an incidental finding at autopsy (Kolln et al., 1972; Pitts and Muecke, 1975). When present, symptoms are typically related to hydronephrosis, infection, tumor, or calculus formation. The most common symptom is vague abdominal pain that may radiate to the lower lumbar region. UTIs occur in 30% of patients, and calculi have been noted in 20% to 80% (Kolln et al., 1972; Pitts and Muecke, 1975; Evans and Resnick, 1981; Sharma and Bapna, 1986; Benchekroun et al., 1998; Cascio et al., 2002). A horseshoe kidney may present as a palpable abdominal mass with or without hydronephrosis (Kolln et al., 1972; Karmi, 1977; Kasper et al., 1976).

Diagnosis and Radiographic Appearance

The classic radiologic features on a plain radiograph of the abdomen include kidneys that are somewhat low lying and close to the vertebral

column and that have a vertical or outward axis with the lower poles being more medial than in the normal kidney (O'Brien et al., 2008). The kidneys may be observed by the delineation of the perinephric fat. Prenatal ultrasonography detects most horseshoe kidneys (Kovo-Hasharoni et al., 1997; Cho et al., 2005). Postnatal ultrasonography detects the isthmus joining the two lower poles of the kidneys in the midline, unless the isthmus is only a thin fibrous band. (Figs. 38.18 and 38.19). Ultrasound diagnosis is made by scanning horizontally along the midline in a craniocaudal direction, especially in children and in thin patients. Radionuclide scanning demonstrates the abnormal axis of a horseshoe kidney. A continuous band across the midline is observed if the isthmus contains functioning parenchyma. CT and MRU can also be used to characterize the isthmus and further evaluate hydronephrosis (see Fig. 38.17). MRA can be used to delineate the vascular anatomy for preoperative planning (O'Brien et al., 2008).

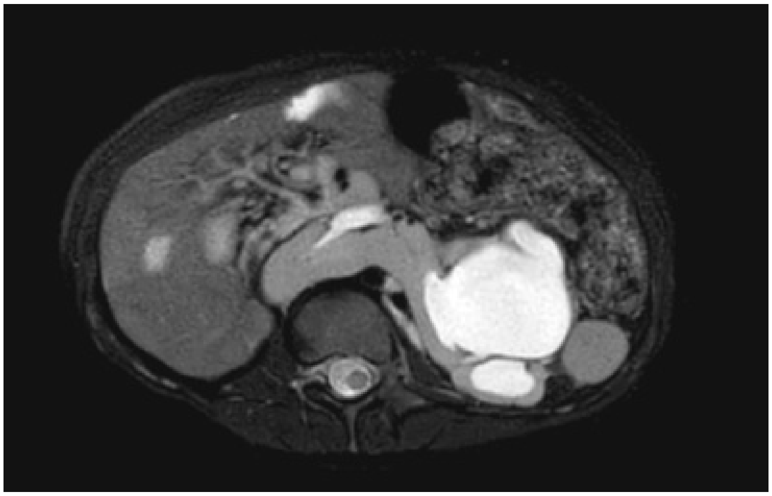

FIG. 38.18 A 16-year-old patient presented with abdominal pain. Computed tomography scan demonstrates horseshoe kidney with severe hydronephrosis of the left side secondary to obstruction of the ureteropelvic junction.

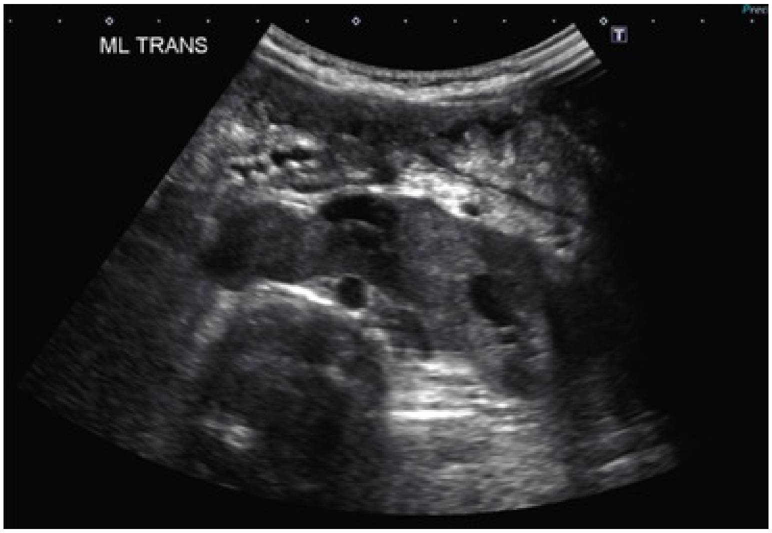

FIG. 38.19 Newborn with cloacal anomaly. Abdominal sonogram shows horseshoe kidney with mild dilation of the right and left collecting system. Note right side with anterior renal pelvis.

Prognosis

Smith and Orkin believed that horseshoe kidneys are almost always associated with disease (Smith and Orkin, 1945); however, **Glenn observed patients with horseshoe kidneys for an average of 10 years after discovery and found that almost 60% of these remained asymptomatic** (Glenn 1959). Only 13% had persistent urinary infection or pain, and 17% developed recurrent calculi. These clinical findings are supported in more contemporary series in which Glodny et al. found that 85% of patients with renal fusion anomalies had no new symptoms appear during follow-up (Glodny et al., 2009). Many disease processes have been described with a horseshoe kidney, but this likely reflects the relative frequency of the congenital defect and subsequent surveillance bias.

Kidney cancers have been reported in patients with horseshoe kidney of varying pathologies (Stimac et al., 2004; Dhillon et al., 2014). **Renal cell carcinoma accounts for about one-half of renal tumors, although the incidence has been found to be no greater than that in the general population** (Buntley, 1976). Cases of bilateral tumors have been reported (Romics et al., 2002). Renal pelvic tumors, Wilms tumors, sarcomas, and carcinoid tumors have also been observed (Isobe et al., 2000; Santiago et al., 2017; Murphy and Zincke, 1982; Nawaz et al., 2014). Overall, 41 of 8617 (0.48%) Wilms tumors in the National Wilms Tumor study occurred in horseshoe kidneys, primarily on the left side, rarely in the isthmus, and practically all with favorable histology (Neville et al., 2002). The incidence of Wilms tumor in horseshoe kidneys is 1.76 to 7.93 times higher than that expected in the general population (Mesrobian et al., 1985). Thirty-seven percent of these Wilms tumors were initially inoperable. However, with preoperative chemotherapy, most patients were salvaged, yielding a 75% preservation rate of renal parenchyma (Neville et al., 2002). Wilms tumor may originate in the isthmus (Beck and Hlivko, 1960). Except for renal pelvic tumors, a surprisingly high number of renal cancers arise in the isthmus (Blackard and Mellinger, 1968). For this reason, it has been suggested that teratogenic factors are responsible for abnormal migration of nephrogenic cells to form an isthmus, which then leads to the horseshoe shape and the predisposition for the development of cancer in this portion of the kidney (Hohenfellner et al., 1992). It has been suggested that the increased occurrence of chronic infection, obstruction, and stone formation explains the higher than expected incidence of renal pelvic tumors because the incidence exceeds that of the general population (Dische and Johnston, 1979). Survival from tumors within the horseshoe kidney is related to the pathology and stage of the tumor at diagnosis and not to the renal anomaly (Dhillon et al., 2014).

Because a horseshoe kidney is located above the pelvic inlet, it should not adversely affect pregnancy or delivery (Bell, 1946b). The development of renal failure associated with adult polycystic kidney disease is no greater in a horseshoe kidney (Correa and Paton, 1976). Because of organ shortage, kidneys with atypical anatomy are frequently considered for transplantation, and renal transplantation has occurred with horseshoe kidneys (Nelson and Palmer, 1975; Zipitis et al., 2003). A horseshoe kidney can be transplanted en bloc, or it can be divided and implanted into two recipients, depending on the anatomy of the vessels and the urinary collecting system. A worldwide review of horseshoe kidney transplant from the Netherlands noted that 23 whole and 57 split horseshoe kidneys have been transplanted, with initial failure rates of only 4.3% and 13.4% for en bloc and for split transplants, respectively. An overall 80% graft survival rate has been reported at 5 years (Stroosma et al., 2001). See Table 38.1.

TABLE 38.1

Summary of Major Anomalies of Renal Number and Position

PATTERN	DESCRIPTION	INCIDENCE	CLINICAL	ASSOCIATE

			ISSUES	**CONDITIONS**
Bilateral renal agenesis	Absence of all renal tissue; 50% incidence of absent ureter/lower urinary tract	Estimated 1 : 5000	Lethal in nearly 100% of cases because of pulmonary hypoplasia	Oligohydramn Potters facies Clubfeet
Unilateral renal agenesis	Absence of unilateral renal tissue, 60% of cases have ipsilateral ureteral agenesis	1 : 1200	Usually asymptomatic Long-term follow-up may have signs of CKD in 30% because of reduced nephron mass	VUR in up to 30% or UPJ obstruction in 10% in contralateral kidney Reproductive anomalies in both sexes in 20% to 40% 30% VACTER patients
Supernumerary kidney	Accessory organ with its own collecting system, blood supply, and distinct encapsulated parenchymal mass	Very rare	Usually asymptomatic	
Simple renal ectopia	Renal tissue that has not fully ascended to orthotopic position and remains on ipsilateral side of which its ureter inserts into the bladder	1 : 900	Hydronephrosis common as a result of anomalies of ascension and rotation	Reproductive anomalies in both sexes in approximately 15
Thoracic kidney	Partial or complete protrusion of the kidney above the	1 : 13,000	Usually asymptomatic	

	kidney above the level of the diaphragm into the posterior mediastinum			
Crossed renal ectopia	Kidney is located on the contralateral side of which its ureter inserts into the bladder	1 : 2000	Potential for hydronephrosis and nephrolithiasis	Anorectal malformations Genitourinary malformations
Horseshoe kidney	Inferiorly fused kidneys at their lower poles, low in abdomen	1 : 400	Potential for hydronephrosis and nephrolithiasis	Anorectal malformations Turner syndro Genitourinary malformations

CKD, Chronic kidney disease; *UPJ,* ureteropelvic junction; *VUR,* vesicoureteral reflux.

Key Points: Horseshoe Kidney

- Horseshoe kidney occurs in 0.25% of the population, or about 1 in 400 individuals.
- The majority of patients with horseshoe kidneys are asymptomatic.
- The calyces, normal in number, are atypical in orientation. Because the kidney fails to rotate, the calyces point posteriorly, and the axis of each pelvis remains in the vertical or obliquely lateral plane.
- Horseshoe kidney is frequently found in association with other congenital anomalies and syndromes.
- The blood supply can be variable, and imaging before surgery may be needed to better delineate.
- UPJ obstruction, causing significant hydronephrosis, occurs in as many as one-third of individuals with horseshoe kidneys, usually from extrinsic compression secondary to atypical ureteral course or crossing aberrant renal vessel.
- Wilms tumors occur more frequently in patients with horseshoe kidneys compared with the general population.

Anomalies of Renal Rotation

The kidney, as it assumes its final position in the "renal" fossa, orients itself so that the calyces point laterally and the pelvis faces medially. When this alignment is not exact, the condition is known as *malrotation*. As mentioned earlier, abnormalities of renal ascent and/or fusion are typically accompanied by abnormalities of renal malrotation. Renal malrotation can occur in orthotopic kidney, and this section focuses on malrotation as an isolated renal entity.

Incidence

Campbell (1963) found renal malrotation in 1 of 939 autopsies, and Smith and Orkin (1945) noted 1 case per 390 hospital admissions. **It is frequently observed in association with Turner syndrome** (Gray and Skandalakis, 1972). Males are affected twice as often as females, but there does not appear to be any predilection for side.

Description

It is thought that medial rotation of the collecting system occurs simultaneously with renal migration. The kidney starts to turn during the sixth week, just when it is leaving the true pelvis, and it completes this process by rotating 90 degrees toward the midline by the time ascent is complete at the end of 9 weeks' gestation. **The kidney and renal pelvis normally rotate 90 degrees ventromedially during ascent.** In a detailed study, Weyrauch categorized the various abnormal phases of medial and reverse rotation according to position of the renal pelvis (Weyrauch, 1939) (see Fig. 38.18).

Ventral Position

The pelvis is ventral and in the same anteroposterior plane as the calyces, which point dorsally because they have undergone no rotation at all. This is the most common form of malrotation.

Ventromedial Position

The pelvis faces ventromedially because of an incompletely rotated kidney. Excursion probably stops during the seventh week of gestation, when the kidney and pelvis normally reach this position. The calyces thus point dorsolaterally.

Dorsal Position

Renal excursion of 180 degrees occurs to produce this rarest position. The pelvis is dorsal to the parenchyma, and the vessels pass behind the kidney to reach the hilum.

Lateral Position

When the kidney and pelvis rotate between 180 degrees and 360 degrees, or when reverse rotation of up to 180 degrees occurs, the pelvis faces laterally and the kidney parenchyma resides medially. The renal vascular supply provides the only clue to the actual direction of excursion. Vessels that course ventral to the kidney to enter a laterally or dorsolaterally placed hilum suggest reverse rotation, whereas a path dorsal to the kidney implies excessive ventral rotation. **In cases of isolated malrotation, other characteristic features may be present** (Patil et al., 2011). The kidney shape may be discoid, elongated, oval, or triangular, with flattened anterior and posterior surfaces. Fetal lobulations are invariably present and are accentuated beyond normal limits. A dense amount of fibrous tissue encases the hilar area, possibly even distorting and fixing the pelvis. The UPJ may be distorted as well. The upper ureter initially courses laterally, and it, too, may be encased in this fibrous matting. The pelvis is elongated and narrow, and calyces, especially the superior calyx, may be stretched. The blood supply may vary widely, depending on the direction and degree of rotation. The vasculature may consist of a single vessel with or without multiple additional branches entering the parenchyma along the course of the renal artery. There also may be a polar vessel in conjunction with the main renal artery. The vascular orientation around the kidney provides the only clue to the type and extent of renal rotation.

Symptoms

Rotation anomalies, per se, do not produce specific symptoms. The excessive amount of fibrous tissue encasing the pelvis, UPJ, and upper ureter, however, may lead to varying degrees of hydronephrosis. Vascular compression from an accessory or main renal artery or distortion of the upper ureter or UPJ may contribute to intermittent obstruction.

Diagnosis

The diagnosis should be considered when a renal calculus is detected in an abnormal location, but confirmation should be obtained from a renal sonogram, CT, MRU, or retrograde pyelogram (Fig. 38.20). These studies show the abnormal orientation of the renal pelvis and calyces, a flattened and elongated pelvis, a stretched superior calyx with blunting of the remaining calyces, and a laterally displaced upper third of the ureter. Bilateral malrotation is not uncommon and may suggest the diagnosis of a horseshoe kidney (Kim et al., 2016). However, careful inspection for an isthmus and observation of the lower pole renal outline should distinguish the two entities.

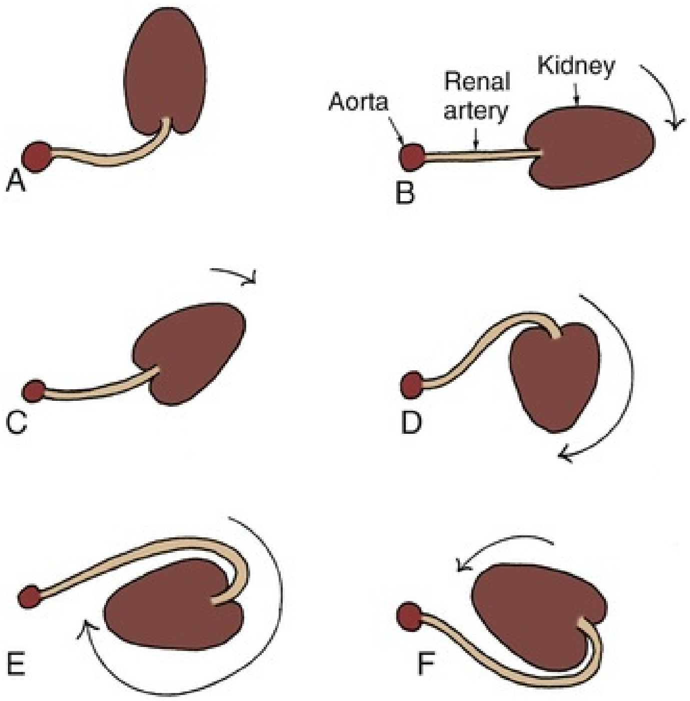

FIG. 38.20 Rotation of the kidney during its ascent from the pelvis. The left kidney with its renal artery and the aorta are viewed in transverse section to show normal and abnormal rotation during its ascent to the adult site. (A) Primitive embryonic position; hilus faces ventrad (anterior). (B) Normal adult position; hilus faces mediad. (C) Incomplete rotation. (D) Hyper-rotation; hilus faces dorsad (posterior). (E) Hyper-rotation; hilus faces laterad. (F) Reverse rotation; hilus faces laterad. (From Gray SW, Skandalakis JE. *Embryology for surgeons.* Philadelphia: Saunders; 1972.)

Prognosis

Malrotation does not impair renal function. Hydronephrosis resulting from impaired urinary drainage may lead to infection and calculus formation (Kim et al., 2016; Tsai et al., 2015).

Key Points: Anomalies of Renal Rotation

- The kidney and renal pelvis normally rotate 90 degrees ventromedially during ascent so that the calyces point laterally and the pelvis faces medially. When this alignment is not exact, the condition is known as malrotation.
- Malrotation is frequently associated with Turner syndrome.

Anomalies of Renal Vasculature

Aberrant, Accessory, or Multiple Vessels

The kidney is divided into various segments, each supplied by a single “end” arterial branch that usually courses from one main renal artery. The preferred term to describe any kidney supplied by more than one vessel originating from the aorta is *multiple renal arteries*. The terms *anomalous vessels* or *aberrant vessels* should be reserved for arteries that originate from vessels other than the aorta or main renal artery. The term *accessory vessels* denotes two or more arterial branches supplying the same renal segment.

Incidence

Between 71% and 85% of kidneys have a single artery that supplies the entire renal parenchyma (Merklin and Michele, 1958; Geyer and Poutasse, 1962). A slightly higher percentage of right-sided kidneys have a single renal artery compared with left-sided organs (Geyer and Poutasse, 1962; Nayak, 2008; Bayramoglu et al., 2003). True aberrant vessels are rare, except in cases with renal ectopia, with or without fusion, and in individuals with a horseshoe kidney (Degani et al., 2010; Glodny et al., 2009; Gesase, 2007).

Embryology

The renal arterial tree is derived from three groups of primitive vasculature that coalesce to form the mature vascular pattern for all retroperitoneal structures. The cranial group consists of two pairs of arteries dorsal to the suprarenal gland that shift dorsally to form the phrenic artery. The middle group is composed of three pairs of vessels that pass through the suprarenal area and retain the same lateral position, becoming the adrenal artery. Finally, the caudal group of four paired arteries cross ventral to the suprarenal area and become the main renal artery. Sometimes the most inferior pair from the middle group joins them (Guggemos, 1962). It is believed that, during renal migration, this network of vessels selectively degenerates, and the remaining adjacent arteries assume a progressively more important function. By a process of elimination, one primitive renal arterial pair eventually becomes the dominant vessel, the completed process being dependent on the final position of the kidney (Graves, 1956). Polar arteries or multiple renal arteries to the normally positioned kidney represent a failure of complete degeneration of all primitive vascular channels. The multiple vessel pattern that has been described for renal ectopia could be considered as an arrested embryonic state for that particular renal position (Gray and Skandalakis, 1972.

Description

Based on vascular supply, the renal parenchyma is divided into five segments: apical, upper, middle, lower, and posterior. The main renal artery divides initially into an anterior and posterior branch. The anterior branch almost always supplies the upper, middle, and lower segments of the kidney. The posterior branch invariably supplies the posterior and lower segments (Sampaio and Aragao, 1990a). The vessel to the apical segment has the greatest variation in origin; it arises from (1) the anterior division (44%), (2) the junction of the anterior and posterior divisions (23%), (3) the mainstem renal artery or aorta (23%), or (4) the posterior division of the main renal artery (10%) (Graves, 1954). Rarely the upper segment is supplied from a branch totally separate from the main renal artery (Merklin and Michele, 1958). Shoja et al. studied the perihilar (extraparenchymal) branching patterns and morphologies of the renal artery (Shoja et al., 2008). A “fork” pattern with a common branching point (usually duplicated) was the most commonly observed extrarenal division and branching pattern of the main renal artery. They conclude that perihilar branching of the main renal artery was highly variable, with predictable patterns in the majority of kidneys. This information is useful for the transplant surgeon when interpreting radiodiagnostics of the renal hilum. **The lower renal segment, however, is often supplied by an accessory vessel.** This vessel is usually the most proximal branch when it arises from the main renal artery or its anterior division (Graves, 1954). However, it may originate directly from the aorta near the main renal artery, or it may be aberrant, arising from the gonadal vessel. Merklin and Michele performed an extensive study of the variant renal and suprarenal blood supply (Merklin and Michele, 1958). Sampaio and Aragao studied the venous drainage of the kidney and noted a close association between the inferior branch to the main renal vein and the anterior inferior aspect of the renal pelvis in 40% of kidneys (Sampaio and Aragao, 1990b).

Symptoms

Symptoms attributable to renal vascular anomalies are those that might result from inadequate urinary drainage at the site of extrinsic compression on the collecting system. Multiple, aberrant, or accessory vessels may constrict an infundibulum, a major calyx, or the UPJ (Addonizio and Patel, 1980; Zambrowicz et al., 1972; Fraley, 1966). Pain and hematuria secondary to hydronephrosis, UTI, or calculus may result.

Diagnosis

Precise anatomic resolution of vascular variants and associated disease states can be obtained using three-dimensional power Doppler ultrasonography, CT, or MRI (Figs. 38.21 and 38.22) (Degani et al., 2010; Leavitt et al., 2013).

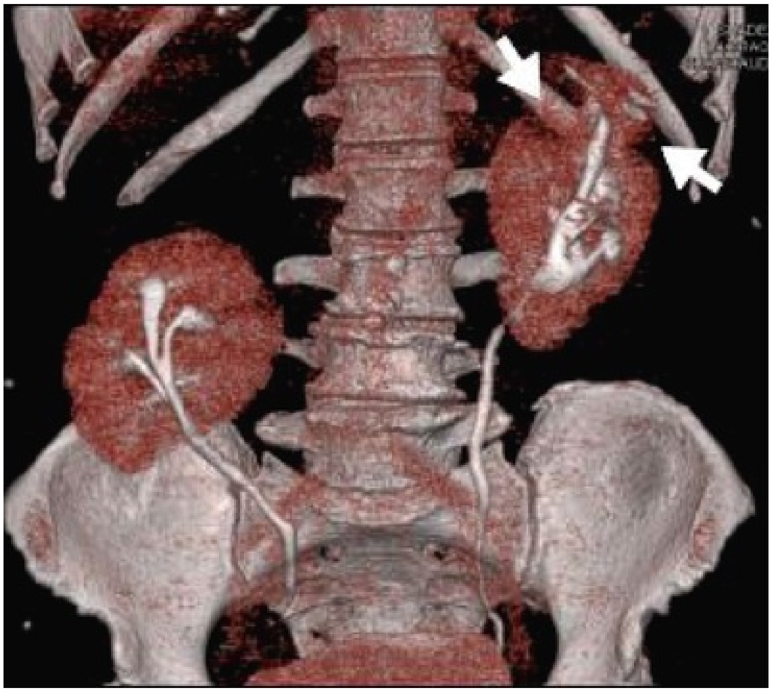

FIG. 38.21 Three-dimensional computed tomography reconstruction image show anteriorly rotated bilateral kidneys in 71-year-old patient with left flank pain caused by acute pyelonephritis. Note wedge-shaped defects in the left upper pole *(arrows).* (From Kim HY, Lee SJ, Bae EH, et al. A case of acute pyelonephritis in bilateral renal malrotation. *Chonnam Med J.* 2016;52:219.)

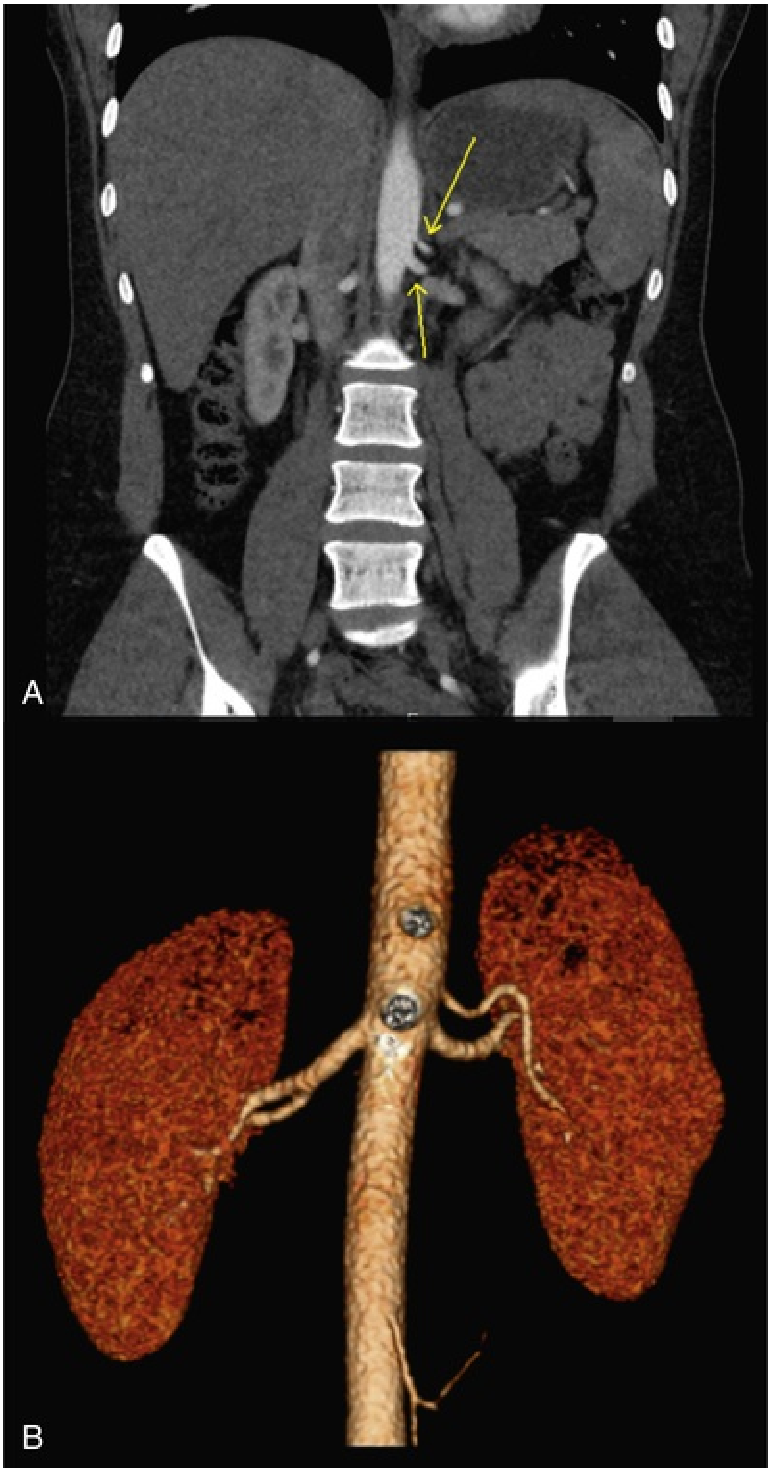

FIG. 38.22 A 29-year-old patient undergoing computed tomography (CT) scanning for living donor renal transplant evaluation. (A) CT scan after administration of intravenous contrast demonstrating renal artery anatomy on coronal images. *Arrows* point to two separate renal arteries arising from aorta. (B) Coronal three-dimensional reconstruction showing single right renal artery and two left renal arteries.

Prognosis

Hydronephrosis secondary to a vascular anomaly such as a lower pole crossing vessel is a very rare finding, especially when one considers the relative frequency of all renal vascular variations. Leavitt et al. reported that the prevalence of crossing vessels in asymptomatic, healthy patients with a radiographically normal ureteropelvic junction was approximately 25% using CT imaging (Leavitt et al., 2013). Zelster et al. used endoluminal ultrasound to identify that a crossing vessel at the UPJ is seen in 19% of patients with a normal UPJ (Zeltser et al., 2004). Hypertension is no more frequent in patients with multiple renal arteries than in those with a single vessel (Geyer and Poutasse, 1962).

Renal Artery Aneurysm

Renal artery aneurysm (RAA) is a rare occurrence, with an estimated incidence of 0.09% in the general population (Stanley et al., 1975). Abeshouse classified RAAs as follows: saccular, fusiform, dissecting, or arteriovenous (Abeshouse, 1951). The saccular aneurysm, a localized outpouching that communicates with the arterial lumen by a narrow or wide opening, is the most common type, accounting for 93% of all aneurysms (Zinman and Libertino, 1982). When the aneurysm is located at the bifurcation of the main renal artery and its anterior and posterior divisions, or at one of the more distal branchings, it is considered to be congenital in origin and is called the *fusiform* type (Poutasse, 1957). The presence of similar aneurysms at branching points in the vasculature of other organ systems attests to this possible origin (Lorentz et al., 1984). Acquired aneurysms may be located anywhere and may result from inflammatory, traumatic, or degenerative factors. A localized defect in the internal elastic tissue and the media allows the vessel to dilate at that point. It is a true aneurysm, because its walls are composed of most of the layers that make up the normal artery (Poutasse, 1957). The outpouchings may vary in size from 1 to 2 cm up to 10 cm (Garritano, 1957), but 90% are smaller than 2 cm. There is no absolute predilection for side, but the right side is more commonly encountered, and bilateral aneurysms are seen in up to 15% (Pfeiffer et al., 2003; Klausner et al., 2015). **In one multi-institutional study in the United States, three-fourths of RAA cases were asymptomatic at diagnosis** (Klausner et al., 2015). **The absence of symptoms predominates when RAA is diagnosed in children** (Sarker et al., 1991). When symptoms are present, they include abdominal or flank pain (6% to 15%), hematuria (microscopic and macroscopic; 5% to 30%), and hypertension (10% to 55%) (Bulbul and Farrow, 1992; Klausner et al., 2015). The hypertension is renin-mediated and secondary to relative parenchymal ischemia (Lorentz et al., 1984). Thirteen cases of hydronephrosis secondary to an adjacent renal vessel aneurysm were noted (Miyagawa et al., 2001). **The diagnosis is suspected when a pulsatile mass is palpated in the region of the renal hilum or when a bruit is heard on abdominal auscultation. A wreathlike calcification in the area of the renal artery or its branches (30%) is highly suggestive** (Silvis et al., 1956). RAAs can be evaluated with color Doppler sonography, spiral CT, three-dimensional MRA, or digital subtraction arteriography (Bunchman et al., 1991; González et

al., 2014).

Many asymptomatic RAAs come to light during a workup of uncontrolled hypertension (35%), whereas 26% are diagnosed when angiography is performed for other reasons (Hupp et al., 1992). **The indications for treatment of RAA remain controversial** (González et al., 2014). **Treatment is indicated for those who present with rupture or are at a high risk for rupture. High risk for rupture is associated with rapidly expanding RAAs and pregnant females, or those who are considering pregnancy.** Several reports exist of a ruptured RAA during pregnancy (Lacroix et al., 2001). The likelihood of spontaneous rupture in the study by Klausner was very low for all RAAs (0.3%), with all ruptured RAAs being larger than 3 cm. Klausner et al., 2015). Among RAAs larger than 3 cm in their study, the rate of rupture was 18%. In addition, intervention is indicated for RAAs larger than 2.0 cm or for individuals with symptoms including uncontrolled hypertension from renal artery stenosis, flank pain, hematuria, or renal ischemia/infarction resulting from embolization from the aneurysm. Open surgical or endovascular techniques should be performed electively for those at high risk for rupture (González et al., 2014; Pfeiffer et al., 2003; Klausner et al., 2015).

Renal Arteriovenous Fistula

Although rare, renal arteriovenous fistulas (AVFs) have been diagnosed with increasing frequency. **Two types exist, congenital and acquired** (Maldonado et al., 1964)**, with the latter (secondary to trauma, inflammation, renal surgery, or percutaneous needle biopsy) accounting for the increase in incidence.** Only the congenital variant is discussed here. **Less than 25% of all AVFs are congenital, with only 91 reported cases** (Takaha et al., 1980; Muraoka et al., 2008)**. They are identifiable by their cirsoid configuration and multiple communications between the main or segmental renal arteries and the venous channels** (Crummy et al., 1965; Cho and Stanley, 1978). Although congenital, they rarely present clinically before the third or fourth decade. Women are affected three times as often as men, and the right kidney is involved slightly more often than the left (Ishikawa et al., 2004). The lesion is usually located in the upper pole (45% of cases), but not infrequently it may be found in the midportion (30%) or in the lower pole (25%) of the kidney (Yazaki et al., 1976). **The condition is thought either to be present at birth or to result from a congenital aneurysm eroding into an adjacent vein** (Thomason et al., 1972).

The pathophysiology involved in the shunting of blood, which bypasses the renal parenchyma and rapidly joins the venous circulation and returns to the heart, results in a varied clinical picture. The symptoms are based on the age and size of the AVF (Messing et al., 1976). **The hemodynamic derangement often produces a loud bruit in 75% of cases. Diminished perfusion of renal parenchyma distal to the fistulous site leads to relative ischemia and renin-mediated hypertension in approximately 50%** (McAlhany et al., 1971). The increased venous return and high cardiac output with concomitant diminution in peripheral resistance may result in left ventricular hypertrophy and subsequent high-output cardiac failure in 50% of cases (Maldonado et al., 1964). Macroscopic and microscopic hematuria occurs in more than 75% of affected individuals because of the proximity of the collecting system (Montoya et al., 2004; Inoue and Hashimura, 2000; Chen et al., 2006; Fogazzi et al., 1997). Although flank or abdominal pain may be present, a mass is rarely palpable (10%). **Three-dimensional Doppler sonography and MRA are accurate and noninvasive tests** (Mohaupt et al., 1999; Macpherson et al., 1991; Ishikawa et al., 2004)**, but selective renal arteriography or digital subtraction angiography is the most definitive method for diagnosing the lesion.** A cirsoid appearance with multiple small, tortuous channels; prompt venous filling; and an enlarged renal, and possibly gonadal, vein are pathognomonic for arteriovenous malformation (AVM) (DeSai and DeSautels, 1973). **The symptomatic nature of this lesion, which causes progressive alterations in the cardiovascular system, often dictates surgical intervention.** The congenital variant rarely behaves like its acquired counterpart, which may disappear spontaneously after several months (Inoue and Hashimura, 2000; Kubota et al., 2003). Nephrectomy, partial nephrectomy, vascular ligation, selective embolization (Bookstein and Goldstein, 1973; Bilge et al., 1999), and balloon catheter occlusion (Bentson and Crandall, 1972) have been used to obliterate the fistula.

Key Points: Anomalies of Renal Vasculature

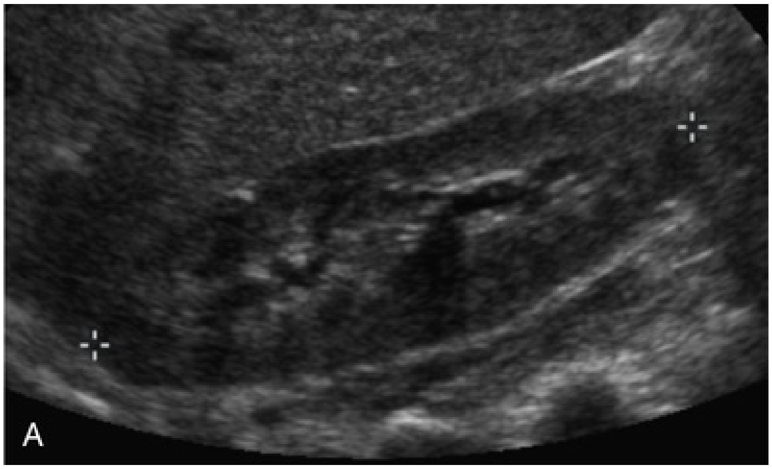
- The overall incidence of RAA is rare and has been calculated to be 0.1%.
- Most RAAs are silent, especially in children. An asymptomatic RAA may be diagnosed during an evaluation for hypertension.

- Treatment of RAA is indicated for those presenting with rupture or at high risk for rupture. Risk factors for RAA rupture are rapidly expanding RAA, RAA greater than 2 cm, pregnancy, or those considering pregnancy.
- Congenital renal AVM RAAs are very rare but may require treatment if alterations in the cardiovascular system occur resulting in high-output cardiac failure.

Anomalies of the Renal Collecting System

Bifid Pelvis

Approximately 10% of normal renal pelves are bifid, the pelvis dividing to form two major calyces first at, or just within, its entrance to the kidney. A bifid pelvis should be considered a normal variant. Further division of the renal pelvis can occur resulting in triplication of the pelvis, but this is extremely rare (Fig. 38.23).



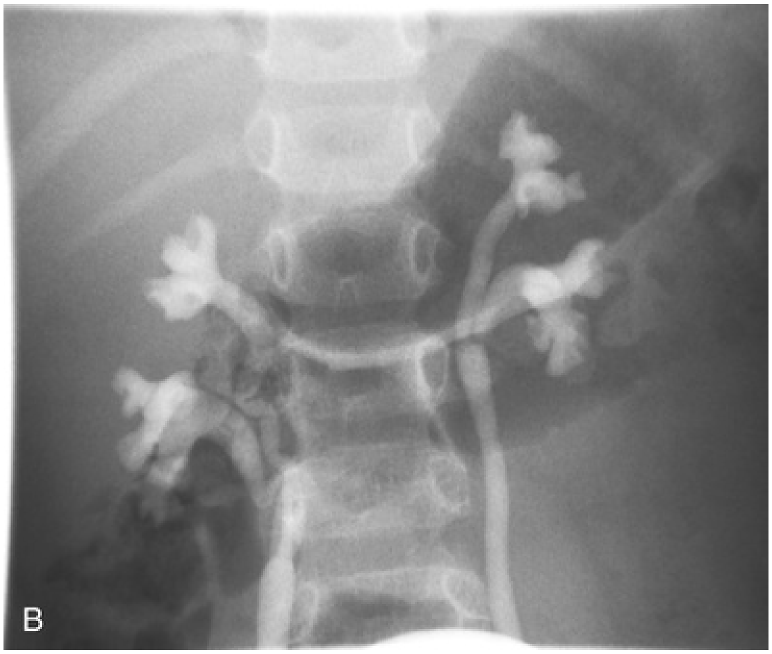


FIG. 38.23 (A) Sonogram showing split hyperechoic region of renal sinus indicative of bifid renal pelvis. (B) Cystogram demonstrating bilateral vesicoureteral reflux into bifid renal pelves.

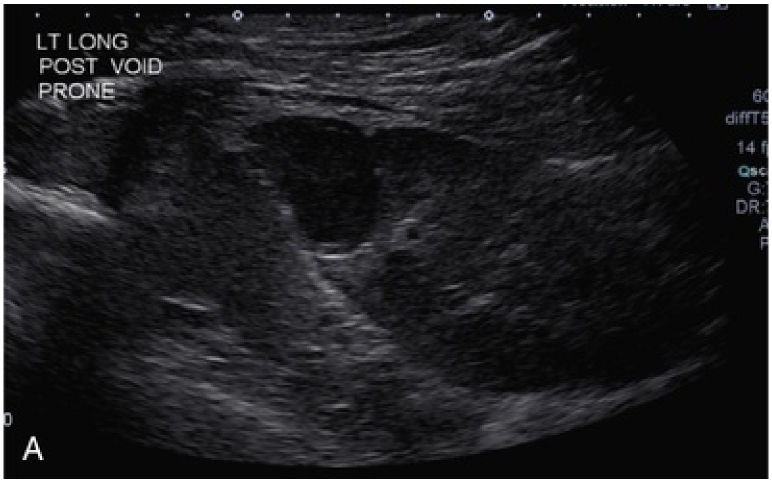
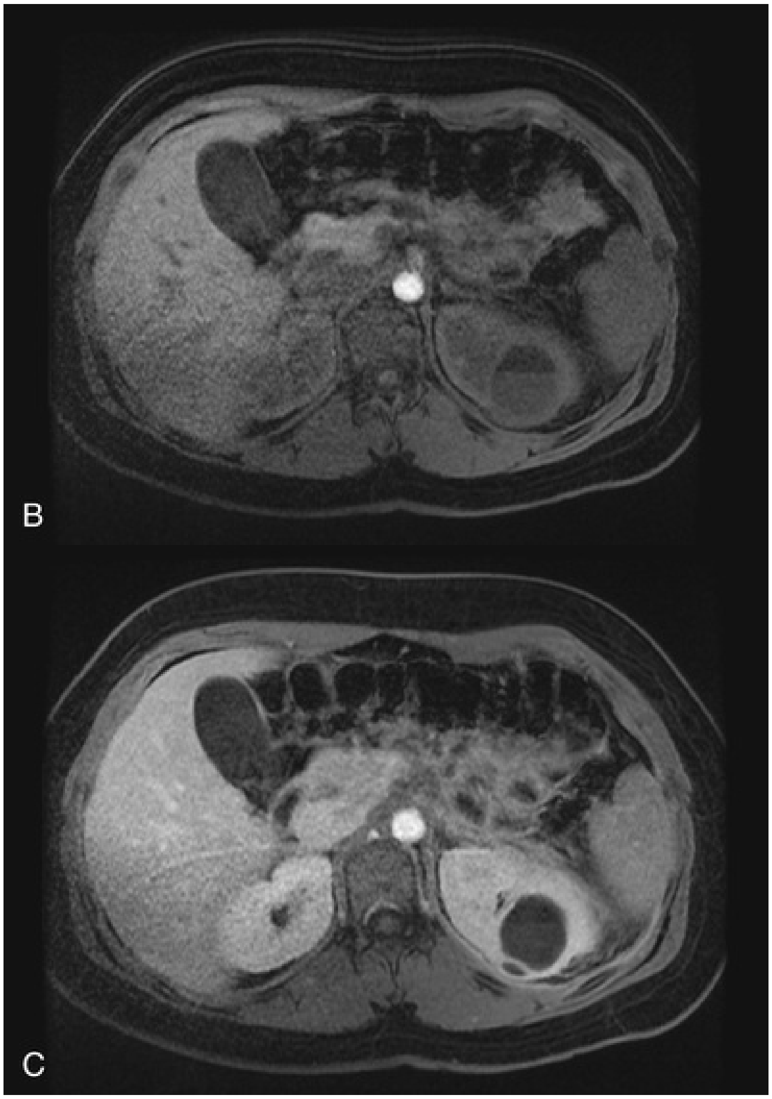
Calyceal Diverticulum

A calyceal diverticulum is a cystic cavity within the kidney that is lined by transitional epithelium and communicates with a calyx or less commonly with the renal pelvis through a narrow isthmus (Estrada et al., 2009)**. An incidence of 4.5 per 1000 has been reported** (Timmons et al., 1975). A similar incidence was noted both in children and in adults, with no predilection for either side or gender. Most diverticula, labeled type I, occur adjacent to an upper or, occasionally, a lower pole calyx. Type II diverticula are larger, communicate with the renal pelvis, and tend to be symptomatic (Wulfsohn, 1980). **Congenital and acquired factors have been suggested to explain the formation of calyceal diverticula.** The similar incidence in children and adults is consistent with an embryologic etiology (Middleton and Pfister, 1974). At the 5-mm stage of the embryo, ureteral branches of the third and fourth generation, which ordinarily degenerate, may persist as isolated branches, resulting in the formation of a calyceal diverticulum (Lister and Singh, 1973). A localized cortical abscess draining into a calyx has also been postulated as an alternative etiologic factor. Amar postulated that calyceal tubular backflow of infected urine could result in abscess formation and parenchymal injury leading to diverticular formation (Amar, 1975). Other proposed causes include obstruction from stones or infection within a calyx, progressive fibrosis of an infundibular stenosis, renal injury, achalasia, and spasm or dysfunction of one of the supposed sphincters surrounding a minor calyx (Siegel and McAlister, 1979; Patriquin et al., 1985). Vesicoureteral reflux has also been considered an etiologic factor.

Small diverticula are usually asymptomatic and are found incidentally by ultrasonography, CT, or MRI (Fig. 38.24). These diverticula may progressively distend with trapped urine and enlarge over time (Amar, 1975; Siegel and McAlister, 1979; Patriquin et al., 1985). Infection, milk of calcium (Patriquin et al., 1985), or true stone formation are complications of stasis or obstruction that can produce symptoms. Lister and Singh, 1973; Siegel and McAlister, 1979). **Hematuria, pain, and UTI may be seen in the presence of stones, which can occur in almost 40% of patients. The diagnosis is suggested on ultrasonography but is confirmed on CT scan or MRU** (Estrada et al., 2009) **(see Fig. 38.24).** Delayed radiographs demonstrate pooling of contrast material in the diverticulum. When it is filled with microcalculi, ultrasonography characteristically demonstrates a layering effect, within the diverticulum, between clear fluid above and echo-dense debris without shadowing below (Widder and Newhouse, 1982). Ultrasonography will image the milk of calcium within the diverticulum as the patient changes position. **Patients who are asymptomatic do not require treatment but should be followed periodically with ultrasonography.** Estrada et al. reported 10 of 23 calyceal diverticula (43%) that required treatment at a mean of 27 months after initial diagnosis (Estrada et al., 2009). Most commonly, these children presented with febrile UTI.





B
C

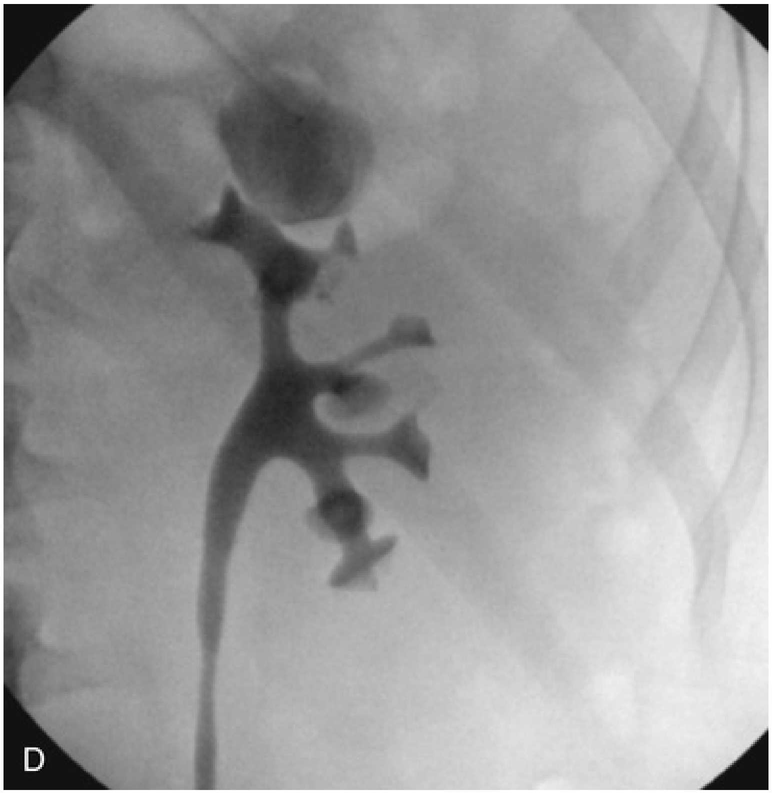


FIG. 38.24 Calyceal diverticulum in a 16-year-old female with recurrent urinary tract infections and left flank pain. (A) Ultrasound of a hypoechoic lesion in the upper pole of the left kidney and no significant hyperemia surrounding the cystic lesion. (B and C) Magnetic resonance axial image of the left kidney precontrast compared with 5 minutes post–intravenous contrast. Images show in upper pole of the left kidney a 3-cm cystic lesion with layering internal contents. (D) Retrograde pyelogram demonstrating injection of contrast into the left ureter and left renal collecting system opacifying the nondilated collecting system and a rounded collection of contrast superior to the collecting system, which was a calyceal diverticulum.

The indications for surgery included enlargement of the diverticulum associated with pain or infection, abscess formation, urosepsis, and symptomatic calculus formation. Retrograde pyelography can delineate the collecting system anatomy before intervention as well (see Fig. 38.24). Ureteroscopy with enlargement of the diverticular communication and removal of the stones has also been reported (Baldwin et al., 1998). Others have performed ureteroscopic ablation of the diverticular cavity to minimize the risk for recurrence (Long et al., 2015). Percutaneous ablation of the communication and fulguration of the diverticular lining is a viable option with favorable long-term results (Monga et al., 2000). Although percutaneous ablation remains a viable treatment alternative, the availability of pediatric laparoscopic equipment has led to the laparoscopic approach for marsupialization of the diverticulum and fulguration of the epithelial lining (Casale et al., 2004; Long et al., 2015; Sripathi et al., 2018).

Hydrocalycosis

Hydrocalycosis is a rare cystic dilation of a major calyx with a demonstrable connection to the renal pelvis. Dilation of the upper calyx resulting from obstruction of the upper infundibulum by vessels or stenosis has been described (Fraley, 1966; Johnston and Sandomirsky, 1972). Cicatrization of an infundibulum may result from infection or trauma or without an obvious etiology (Williams and Mininberg, 1968). It has been postulated that achalasia of a ring of muscle at the entrance of the infundibulum into the renal pelvis causes a functional obstruction (Williams and Mininberg, 1968). Mild upper calyceal dilation caused by partial infundibular obstruction is relatively common but usually asymptomatic. Although the most frequent presenting symptom is upper abdominal or flank pain, hydrocalycosis may be detected on prenatal ultrasonography. On occasion, a mass may be palpated. Stasis can lead to hematuria, urinary infection, or both. Hydrocalycosis must be differentiated from multiple dilated calyces secondary to ureteral obstruction, calyceal clubbing as a result of recurrent pyelonephritis or medullary necrosis, renal tuberculosis, a large calyceal diverticulum, and megacalycosis.

Megacalycosis

Megacalycosis is defined as nonobstructive enlargement of calyces resulting from malformation of the renal papillae (Fig. 38.25). The calyces are generally dilated and malformed and may be increased in number (12 to 20) (Pieretti-Vanmarcke et al., 2009). The renal pelvis is not dilated, nor is its wall thickened, and the UPJ is normally funneled without evidence of obstruction. The cortical tissue around the abnormal calyx is normal in thickness. The medulla, however, is underdeveloped and assumes a falciform (crescent) or semilunar appearance instead of its normal pyramidal shape. The collecting tubules are not dilated but are definitely shorter than normal, and they are oriented transversely rather than vertically from the corticomedullary junction (Puigvert, 1963). A mild disorder of maximal concentrating ability has been reported (Gittes and Talner, 1972), but acid excretion is normal after an acid load

(Vela-Navarrete and Garcia Robledo, 1983). Other functions of the kidney such as glomerular filtration, renal plasma flow, and isotope uptake also are not altered (Gittes, 1984). Turkmen et al. reported of a case of IgA nephropathy diagnosed in the setting of acute kidney injury and bilateral megacalycosis (Turkmen et al., 2013).

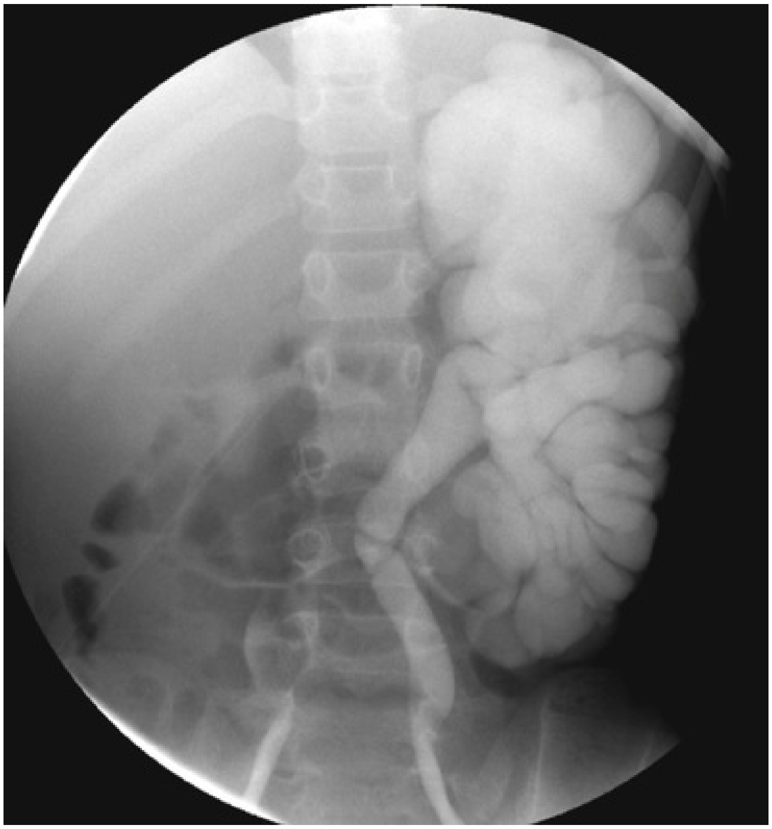

FIG. 38.25 Voiding cystogram demonstrating bilateral vesicoureteral reflux, right grade 1 and left side with innumerable dilated calyces and nondilated renal pelvis diagnostic of megacalycosis.

Megacalycosis is congenital and has been diagnosed prenatally (Hill et al., 2002)**. It occurs predominantly in males with a ratio of 6 : 1 and has been found only in Caucasians. Bilateral disease has been seen almost exclusively in males, whereas segmental unilateral involvement occurs only in females** (Cacciaguerra et al., 1996). It was theorized by Puigvert and endorsed by Johnston and Sandomirsky that there is a transient delay in the recanalization of the upper ureter after the branches of the UB hook up with the metanephric blastema (Puigvert, 1964; Johnston and Sandomirsky, 1972). This produces transient obstruction when the glomeruli start producing urine. The fetal calyces may dilate and retain their obstructed appearance, despite the lack of evidence of obstruction in postnatal life (Gittes and Talner, 1972). **The increased number of calyces may be an aborted response by the branching UB to the obstruction.** The abnormality is usually diagnosed during radiographic evaluation for UTI or other congenital anomalies (Arambasic et al., 2003). Adults frequently present with hematuria secondary to renal calculi. The calyces are dilated and are usually increased in number, but the infundibuli and pelvis may not be enlarged (see Fig. 38.25). Although the UPJ does not appear obstructed, there may be segmental dilation of the distal third of the ureter (Kozakewich and Lebowitz, 1974; Mandell et al., 1987). A normal-caliber ureter was interposed between the two entities. This anatomic picture may be mistaken for congenital ureteropelvic, ureterovesical junction obstruction, or infundibular stenosis (Pieretti-Vanmarcke et al., 2009). Diuretic renography shows a normal pattern for uptake and washout of the isotope (Gómez Tellado et al., 1997). **Long-term follow-up of these patients does not show progression of the anatomic derangement or functional impairment of the kidney** (Gittes, 1984).

Infundibulopelvic Stenosis

Infundibulopelvic stenosis most likely forms a link between cystic dysplasia of the kidney and the grossly hydronephrotic organ (Uhlenhuth et al., 1990). This condition includes a variety of radiographically dysmorphic kidneys with varying degrees of infundibular or infundibulopelvic stenosis that may be associated with renal dysplasia (Fig. 38.26). It is believed that this was the result of extensive dysgenesis of the pyelocalyceal system but with preservation of renal function. **Infundibulopelvic stenosis is usually bilateral and is commonly associated with vesicoureteral reflux, suggesting an abnormality of the entire UB** (Kelalis and Malek, 1981). Patients usually present with urinary infection, hypertension, or flank pain. Sometimes, an asymptomatic child with multiple anomalies is found to have this condition. Dally et al. reported a series of 200 patients with MCDK in which 5 patients had infundibulopelvic stenosis in the contralateral kidney (Dally et al., 2011). The MCDK was diagnosed in the first year of life in four of the five patients in the study. The infundibulopelvic stenosis was diagnosed early (before 1 year of age) in two patients while it was diagnosed later (6, 12, and 16 years of age). Despite extensively dysmorphic kidney features, the function is either normal or only slightly affected (Kelalis and Malek, 1981; Dally et al., 2011). In Husmann's study of 21 patients with the longest follow-up to date (median of 11 years), 90% had bilateral renal disease (Husmann et al., 1994). Ten patients had bilateral infundibulopelvic stenosis, six had a contralateral dysplastic renal unit, and three had contralateral URA. Renal insufficiency or ESRD developed in eight patients (37%), all of whom had bilateral kidney anomalies. Renal biopsies in those with ESRD demonstrated renal dysplasia proximal to the stenotic infundibuli and varying degrees of glomerulosclerosis of the glomeruli that were not involved in the regions with dysplasia. They proposed that the decreased total functional renal tissue leads to hyperfiltration injury. They suggested that endoscopic or percutaneous surgery should be considered for increasing hydronephrosis. Nurzia et al. recommend monitoring of renal function to include a baseline and yearly serum creatinine level, estimation of glomerular filtration rate, and urinalysis (Nurzia et al., 2002). Prevention of hyperfiltration injury with calcium-channel–blocking agents, ACE inhibitors, and dietary restriction of protein should be considered when a decline in renal function occurs (Puddu et al., 2009). Surgical intervention should be reserved for patients in whom obstruction from the infundibulopelvic stenosis is demonstrated to negatively affect renal function. Bayne and Peters reported on three patients who each underwent open repair for declining renal function (Bayne and Peters, 2016). As a surgical strategy to optimize postoperative outcomes, the authors advocate for utilization of preoperative three-dimensional modeling via MRU to guide proper placement of calicocalicostomy drainage to a lower pole ureterocalicostomy.

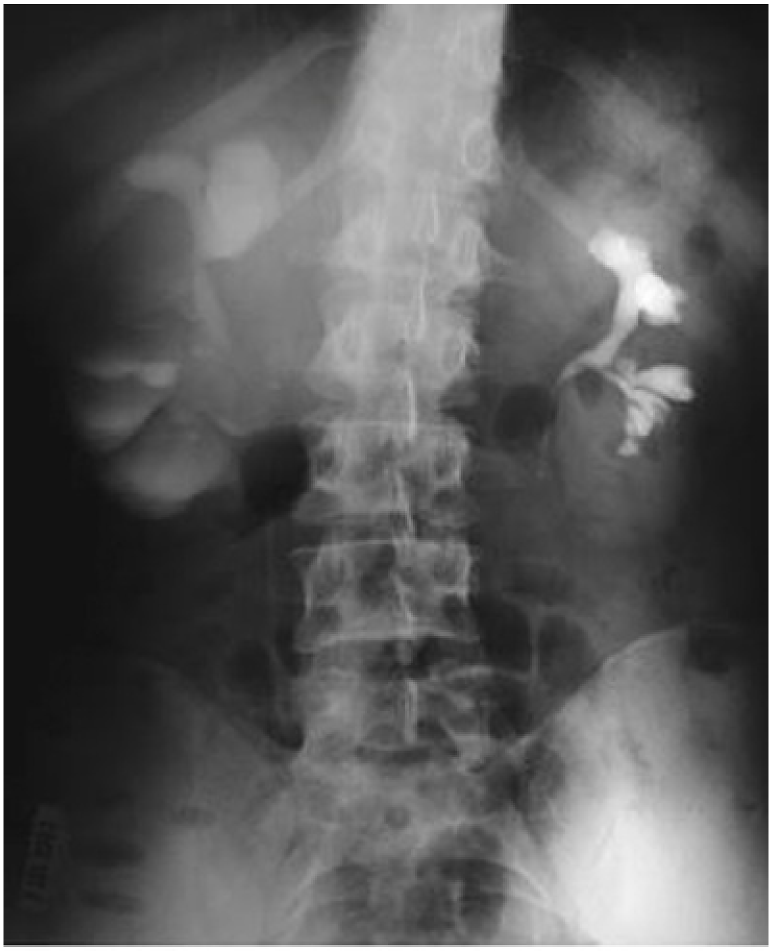

FIG. 38.26 Intravenous pyelogram of a 17-year-old boy showing severe right calyceal dilatation, no dilation of the right renal pelvis, and a small contralateral renal pelvis. The left renal pelvis is slightly atrophic, an infundibulopelvic stenosis variant. (From Bayne CE, Peters CA. Congenital infundibulopelvic stenosis: indications for intervention, surgical technique, and review of literature. *J Ped Urol*. 2016;12:389.)

Key Points: Anomalies of Renal Collecting System

- Calyceal diverticulum is a cystic cavity within the kidney that is lined by transitional epithelium and communicates with a calyx or, less commonly, with the renal pelvis through a narrow isthmus.
- The diagnosis of calyceal diverticulum is best made by CT or MRU.
- Endoscopic or laparoscopic treatment are both effective approaches for treatment of symptomatic calyceal diverticulum.

- Megacalycosis is a congenital, nonobstructive enlargement of calyces resulting from malformation of the renal papillae.
- Infundibulopelvic stenosis is usually bilateral, and despite extensively dysmorphic kidney features, the function is either normal or only slightly affected.

Acknowledgments

The authors would like to acknowledge the efforts and assistance of Dr. Steven Kraus in compiling a portion of the radiographic images included in this chapter. The authors would also like to acknowledge Drs. Ellen Shapiro and Shpetim Telegrafi for their work on this chapter in the previous edition.

Renal Dysgenesis and Cystic Disease of the Kidney

John C. Pope IV, MD

Congenital and acquired renal malformations constitute a wide spectrum of clinical entities. This chapter is devoted to those disorders that lead to dysgenesis of the kidney, cystic lesions of the kidney, or both.

Many of these conditions are related to maldevelopment of the kidney and urinary tract and are thus the result of anomalous genetic mechanisms, some of which are understood and others of which are not. A basic knowledge of molecular genetics is required to better understand normal renal development, absence of renal development, and the effects of genetic mutations and abnormal signaling proteins on renal maldevelopment and cystic diseases. Within this chapter, the relevant genetic processes are briefly discussed as they relate to specific disease processes.

Overview of Genetics

Genetic direction of kidney and urinary tract development results when a gene from a specific chromosomal area produces a protein product that then signals certain actions to occur within an individual cell or group of cells. This cellular differentiation is then responsible for the particular action of those cells. In general, when a gene is normal, its protein product is normal as well. When a gene is abnormal, it produces an abnormal protein that can lead to maldevelopment or disease. Obviously, with complex organogenesis, the process is not always this simple. Often **more than one gene can be responsible for a specific disease. For example, an abnormality of one of two genes is responsible for the entity tuberous sclerosis. One tuberous sclerosis gene, *TSC1*, is located on chromosome 9 and the second, *TSC2*, on chromosome 16.**

Each gene within a cell is one of a set of two; each is called an *allele*. One defective allele may be the carrier for the defect**. In Knudson's** (1971) **two-hit theory, the first hit is an inherited mutation that is found in all cells of an individual (i.e., a germline mutation). The second hit occurs when the wild-type, normal allele spontaneously mutates within a specific organ, although it may be a different mutation than in the primarily affected allele**. For example, the typical somatic cells in the kidney and all other cells of a patient with von Hippel-Lindau (VHL) disease typically are heterozygous for the *VHL* gene located on chromosome 3; that is, the mutant *VHL* allele is inherited and its mate is the normal wild-type allele. However, the configuration of wild-type *VHL* makes it prone to spontaneous mutation. If the wild-type allele develops a defect within the cells of a specific organ, those cells no longer are able to produce normal pVHL (VHL protein) with its suppressor properties. That organ then has the propensity to develop a tumor. The variability in manifestations of autosomal dominant polycystic kidney disease (ADPKD) may be related to a two-hit phenomenon as well. For example, ADPKD is a heterozygous condition in which one allele of the *PKD1* or *PKD2* set is responsible for the genetic transmission of the disease but may not be enough for cystogenesis. A spontaneous mutation of the wild-type allele may be responsible for cystogenesis or for other manifestations of the disease.

Renal Agenesis and Dysplasia

Many terms can be used to describe anomalous development of the kidney. These terms are often used interchangeably and can result in great confusion. The definitions as adopted in 1987 by the American Academy of Pediatrics (AAP) Section on Urology (Glassberg et al., 1987) are used in this chapter.

Renal Agenesis

See Chapter 38.

Renal Dysplasia

Definition

Renal dysgenesis is defined as maldevelopment of the kidney that affects its size, shape, or structure. It is composed of two primary subtypes, the first of which is dysplasia. The term *dysplasia*, although literally and most simply is defined as “abnormal tissue,” specifically, as it relates to the kidney, can only truly be defined on the basis of histopathology. **Dysplasia is a histologic diagnosis made by the presence of embryonic, immature mesenchyme, and primitive renal components.** The differentiation of the metanephros into mature renal components halts at some point along the developmental pathway, often because of an error in the wolffian duct–ureteric bud–metanephric blastema interaction. Common histologic features include distortion of renal architecture, immature or primitive glomeruli, nephron precursors such as comma- and S-shaped bodies, and cartilage and tubules encircled by collars of fibromuscular cells (referred to as *primitive ducts*) (Fig. 39.1). Ericsson and Ivemark (1958) considered these primitive ducts to be the sine qua non finding of all dysplasia. Cysts may or may not be present. The cause of the development of dysplasia appears to be twofold: (1) a primary, inherent abnormality in the differentiation of the nephron and collecting duct, often with an underlying genetic cause, and (2) a secondary cause resulting from congenital urinary tract obstruction.

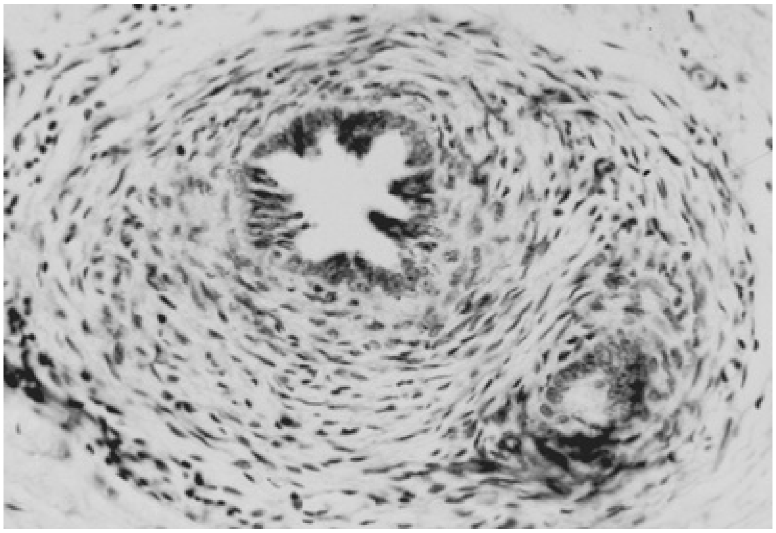

FIG. 39.1 Primitive duct lined with columnar epithelial cells. Note concentric arrangement of spindle mesenchymal cells around the duct. Special staining is required to demonstrate smooth muscle cells.

Key Points: Dysplasia

- The hallmark of dysplasia is the primitive duct, a duct encircled by a collar of fibromuscular cells.
- Dysplasia in its truest form is a histopathologic definition, not a clinical one.
- Dysplasia often is associated with ureteric bud anomalies and/or urinary tract obstruction.

Etiology

Renal dysplasia is the primary cause of childhood end-stage renal disease (ESRD), and two main theories have been considered in its pathogenesis: (1) a primary failure of ureteric bud activity and (2) a disruption in renal development produced by fetal urinary outflow impairment (obstruction). Mackie and Stephens (1975) described the ureteric bud theory, suggesting that ectopic (cephalad or caudal) ureteric bud formation leads to abnormal ureteric orifice location either laterally (often leading to vesicoureteral reflux) or distally (often leading to ureteral obstruction). Normal nephrogenesis is dependent on the ureteric bud meeting the center of the metanephric mesenchyme so that nephrogenesis is appropriately induced by the ureteric bud. However, an abnormally located ureteric bud would be expected to penetrate into a peripheral, degenerating area of the metanephric blastema. The result is a marginal (i.e., hypoplastic or dysplastic) kidney. In cases of dysplasia that are associated with an ectopic ureter, it is not clear if it is the obstruction, aberrant ureteric bud–metanephros interaction, or some other factor that leads to the dysplasia. Dysplasia associated with vesicoureteral reflux would also be included in this category.

Currently, there is no direct experimental evidence to prove that an abnormal ureteric bud site leads to ureteric bud penetration at a peripheral area of the blastema. However, there are substantial data to support the idea that defects in genetic and apoptotic pathways can affect ureteric bud formation, branching morphogenesis within the metanephric blastema, and normal nephrogenesis (Grieshammer et al., 2004; Mendelsohn et al., 1994; Norwood et al., 2000; Pope et al., 2001; Thomas et al., 2005).

Animal studies of fetal urinary tract obstruction generate some but not all of the anatomic and histopathologic features of human renal dysplasia. Findings in these animal studies include dilation at various segments of the nephron and collecting duct, inhibition of nephron development in the nephrogenic zone, architectural disorganization, and the appearance of primitive glomeruli as well as S-shaped bodies and cysts. At times, obstruction in these animal models can even lead to de-differentiation of certain cells. An example is the conversion of renal epithelial cells back into mesenchymal cells and even of mesenchymal cells into myofibroblasts (Matsell and Tarantal, 2002; Nguyen et al., 1999; Peters et al., 1992). Dysplasia arising from obstruction typically appears at the periphery of the kidney, at the nephrogenic zone, and frequently with subcapsular cysts. This type usually develops later in gestation, as in the case of posterior urethral valves (PUVs) (Fig. 39.2).

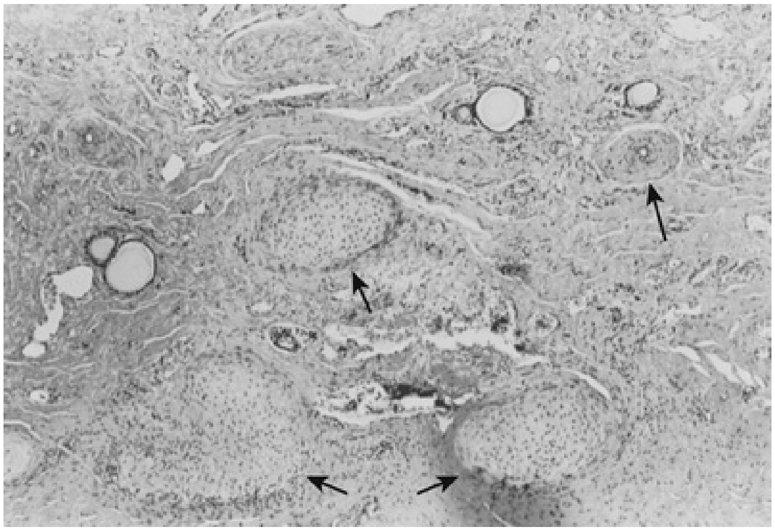

FIG. 39.2 Histologic specimen of a nonfunctioning reflux kidney in a patient with posterior urethral valves. Note presence of nests of cartilage *(short arrows).* Primitive ducts are scattered throughout the specimen *(long arrow)* (100×). The findings are compatible with dysplasia.

Dysplasia is associated with numerous genetic syndromes (e.g., Fraser syndrome; branchio-oto-renal [BOR] syndrome; renal-coloboma syndrome; Kallmann syndrome; Simpson-Golabi-Behmel syndrome; Smith-Lemli-Opitz syndrome; hypoparathyroidism, sensorineural deafness, and renal dysplasia [HDR] syndrome, and Townes-Brocks syndrome). The kidney, in association with these conditions, may be composed mostly of normal functioning parenchyma with areas of dysplasia, or, alternatively, the entire kidney may be dysplastic or entirely absent.

Ultrasonographically, dysplastic kidneys have a distinct appearance. The kidney is typically small and is hyperechogenic when compared with the liver. There is loss of the typical corticomedullary differentiation, and there is minimal distinction of the renal parenchyma and the perirenal fat (Fig. 39.3A). Cysts can be seen in conjunction with parenchymal dysplasia (Fig. 39.3B). The exact cause of the cyst formation is unclear. The important point is that not all cysts are a result of dysplasia, and not all dysplasia is associated with cysts.

Hypoplasia and Hypodysplasia

Renal Hypoplasia

Another form of renal dysgenesis is hypoplasia, which is defined as the underdevelopment of a tissue or organ and is usually caused by a deficiency in the number of cells. Renal hypoplasia is a condition in which there is a reduction in the size of the functioning renal mass. Use of the term *hypoplasia* should be restricted to kidneys that have less than the normal number of calyces and nephrons but are not dysplastic or embryonic. These are kidneys that are morphologically normal but have either a reduced number of nephrons or smaller nephrons, although a hypoplastic kidney may have a normal nephron density despite its small size. Hypoplasia may be bilateral or unilateral. In unilateral cases, the other kidney usually shows greater compensatory growth than is characteristic in patients with renal atrophy caused by acquired disease. Many have used the term *hypoplasia* to describe small kidneys associated with vesicoureteral reflux. These kidneys often do not function and have dysplastic elements histologically. The term *hypoplasia* is thus technically incorrect, and a more appropriate term for these kidneys would be *congenital reflux nephropathy.* The terms *hypoplasia* and *congenital reflux nephropathy* should *not,* however, be used interchangeably. Small kidneys associated with reflux have been called *hypoplastic* in the past; however, now the term *reflux nephropathy* is used to describe the renal changes associated with reflux.

Hypodysplastic kidneys most often occur in conjunction with ectopic ureteric orifices, with the extent of dysplasia correlating with the degree of ectopia (Schwarz et al., 1981). However, hypodysplastic kidneys are seen in a few patients with normal ureteric orifices. In such patients, obstruction may or may not be present.

All forms of hypoplasia can be assessed by ultrasonography with measurement of the kidneys. The size will be reduced in all forms. Dilated calyces may also be seen. Renal function is assessed biochemically and, if there is unilateral hypoplasia, by radionuclide studies.

Oligomeganephronia

First described in 1962 (Habib et al., 1962; Royer et al., 1962), oligomeganephronia is a type of renal hypoplasia that results from a quantitative defect of the renal parenchyma with a reduced number of nephrons and hypertrophy of each nephron. This condition differs histopathologically from simple hypoplasia, in which the renal mass is reduced but the number of nephrons is normal. It is usually a bilateral condition, although a few instances of unilateral oligomeganephronia associated with contralateral renal agenesis have been reported (Forster and Hawkins, 1994; Griffel et al., 1972; Lam et al., 1982).

Etiology

Oligomeganephronia results from arrested development of the metanephric blastema at 14 to 20 weeks' gestation, with subsequent hypertrophy of glomeruli and tubules (Fig. 39.4) in the kidney. This hypertrophy and hyperfiltration results in further nephron injury and sclerosis. Eventually, this progressive loss of nephrons leads to ESRD. Recently, genetic mutations have been described in association with oligomeganephronia (Bohn et al., 2003) as have vascular abnormalities and accidents. The cause of most oligomeganephronia cases is unknown.

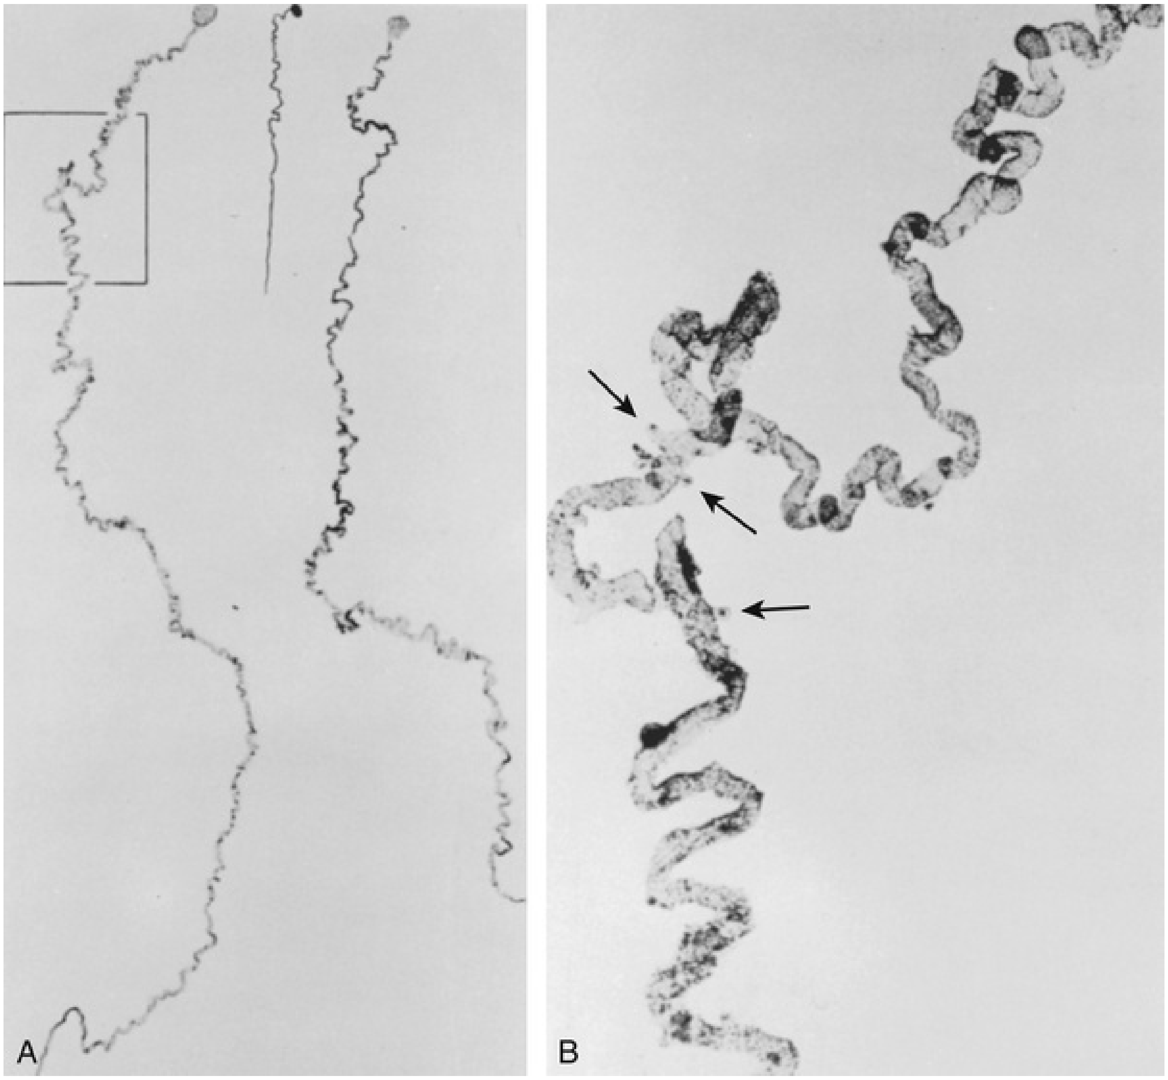

FIG. 39.4 (A) Mosaic photograph of two typical proximal tubules dissected from the kidney of a patient with oligomeganephronia. The silhouette in the top center is a diagrammatic representation to scale of an average proximal tubule from a kidney of an age-matched control. (B) Enlargement of the *inset* in A showing the diverticula along the course of the nephron *(arrows).* (From Fetterman GH, Habib R: Congenital bilateral oligonephronic renal hypoplasia with hypertrophy of nephrons [oligomeganephronia]. *Am J Clin Pathol* 52:199–207, 1969.)

Clinical Features

Oligomeganephronia is a nonheritable congenital disorder, and boys appear to be affected more often than girls. It frequently is associated with low birth weight (2500 g). The condition is usually discovered within the first 2 years of life. In neonates, kidney disease is often suspected with spontaneous pneumothorax, feeding problems, or laboratory abnormalities and may also be incidentally diagnosed when renal anomalies are discovered in the evaluation of another illness. The creatinine clearance is abnormal (10 to 50 mL/min/1.73 m^2), and the maximum specific gravity of the urine is 1.007 to 1.012. Moderate proteinuria may be present, but this is more likely to be a later finding. In neonates with oligomeganephronia, particular attention should be directed to diagnosis of associated syndromes, including BOR syndrome, acrorenal syndrome, and tapetoretinal dystrophia.

After the first year of life, individuals with oligomeganephronia most often have short stature, polyuria and polydipsia, or proteinuria. Renal function remains below normal (although stable) for many years. As the patient enters his or her teens, the creatinine clearance begins to drop rapidly. Marked proteinuria (2 g/24 h) is common. Over a period of years, the kidney continues to atrophy with reduction in the number of tubules. Oligomeganephronia is a progressive disorder, and many patients progress to renal failure in the second decade.

Histopathology

Meticulous histologic examination of the kidney is the only way to establish an absolute diagnosis of oligomeganephronia. There is a reduced number of nephrons and immature glomeruli are often present. Existing glomeruli and tubules are enlarged. As the disease progresses, segmental sclerosis and hyalinosis of glomeruli are present. Tubular atrophy with interstitial fibrosis occurs. The renal artery is small.

Evaluation

Proteinuria is often the first laboratory manifestation of oligomeganephronia and precedes decline in renal function by several years. Other laboratory manifestations of renal failure are frequently present, including elevated blood urea nitrogen (BUN) and creatinine levels, hyponatremia, and metabolic acidosis. Small kidney size depicted on renal ultrasonography (RUS) usually establishes the diagnosis of hypoplasia.

Treatment

In general, treatment is supportive and directed at maintaining normal biochemical balance, hemoglobin, and growth. High fluid intake and correction of salt loss and acidosis are the initial steps. Daily dietary protein should be limited to 1.5 g/kg during the stable phase (Royer et al., 1962). In addition, angiotensin-converting enzyme (ACE) inhibitors may be of benefit in slowing progression of renal failure, even if the patient has a normal blood pressure (BP). ESRD is managed by dialysis and transplantation. The allograft may come from a living related donor because the disease is not familial.

Ask-Upmark Kidney (Segmental Hypoplasia)

Segmental renal hypoplasia, or Ask-Upmark kidney, refers to situations of extreme acquired reflux nephropathy, and the patients (usually young women and girls) most frequently have hypertension. The lesions found in these kidneys are most likely acquired, possibly representing chronic atrophic pyelonephritis caused by vesicoureteral reflux, although some appear to be congenital. Segmental vascular (arterial) anomalies have also been cited as a possible cause for these lesions.

Clinical Features

Most patients are 10 years of age or older at diagnosis. The disease is associated with severe hypertension, sometimes with headaches, either alone or together with hypertensive encephalopathy (Rosenfeld et al., 1973) and with retinopathy in half of the patients (Royer et al., 1971).

Proteinuria and some degree of renal insufficiency may be present if the disease is bilateral. The disorder is usually unilateral, producing a small kidney with deep, narrow, segmental scars (slit-scar) found in the midzone. These slit-scars are the classic radiographic finding. Although the scar can be detected with ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI), the presence of a deep scar is often overlooked.

Histopathology

The Ask-Upmark kidney is smaller than normal—12 to 35 g (Royer et al., 1971). Its distinctive feature is one or more deep grooves on the lateral convexity, underneath which the parenchyma consists of tubules resembling those in the thyroid gland. Usually, the hypoplastic segments are easily distinguished from adjacent areas. The medulla consists of a thin band, and remnants of the corticomedullary junction and arcuate arteries are seen. Arteriosclerosis is common, and juxtaglomerular hyperplasia may be seen (Fig. 39.5; Arant et al., 1979; Bernstein, 1968; Kaufman and Fay, 1974; Meares and Gross, 1972).

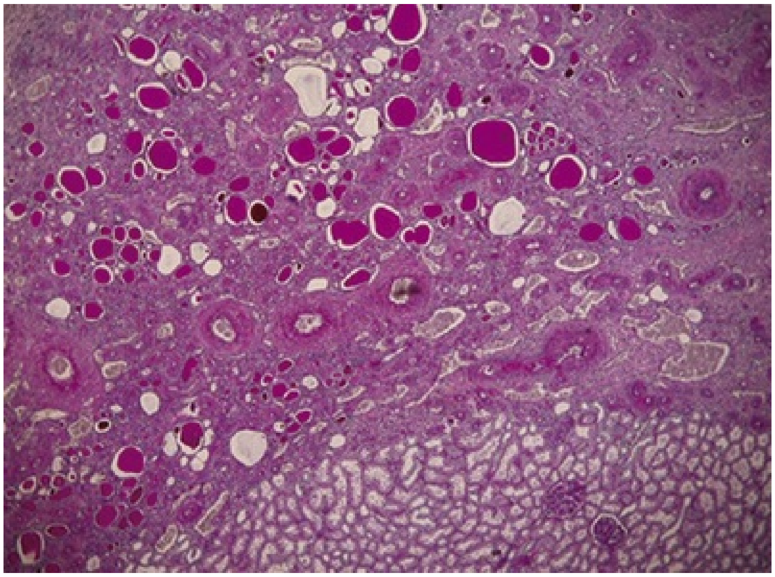

FIG. 39.5 Typical microscopic pattern of segmental hypoplasia affecting the cortex with thyroidlike tubules, thick-walled arteries, and the absence of glomerulus. Note the sharp delineation from the surrounding normal kidney *(bottom)*. Periodic acid–Schiff stain. (From Babin J, Sackett M, Delage C, et al.: The Ask-Upmark kidney: a curable cause of hypertension in young patients. *J Hum Hypertens* 19:315–316, 2005.)

Treatment

Abnormal renin secretion has been proposed as the cause of the hypertension; however, nephrectomy has been shown to normalize BP regardless of plasma renin activities (Babin et al., 2005). In patients with unilateral disease, partial or total nephrectomy may control the hypertension (Meares and Gross, 1972; Royer et al., 1971). Failure of this measure suggests an unrecognized scar or generalized arteriosclerosis in the remaining kidney (Arant et al., 1979). Bilateral disease with renal insufficiency usually is managed medically, although dialysis and transplantation may be needed. Correction of reflux may prevent further renal damage but probably will have no effect on the hypertension.

Renal Hypodysplasia

Hypodysplasia may be associated with a wide spectrum of urologic diseases, such as primary obstructive megaureter, ureterocele, urethral obstruction, or prune-belly syndrome. Lateral ureteral ectopia usually leads to vesicoureteral reflux and its associated forms of hypodysplasia. Medial ureteral ectopia, with or without the presence of a ureterocele, can often result in hypodysplasia as well.

The renal cortex may be thin, secondary to hydronephrosis, or severely dysplastic, and perhaps with numerous small cysts.

According to Osathanondh and Potter (1964), posterior urethral valves may be associated with two types of renal hypodysplasia. In the less severe form, there are small, usually subcapsular cysts and nearly normal renal function. In the second form, the cysts are larger and more widely distributed, and numerous islands of cartilage are present. This form usually is associated with earlier onset and more severe obstruction and reflux (see Fig. 39.2).

The features of prune-belly syndrome (absent abdominal musculature, triad syndrome) include grossly deformed kidneys, which may have various degrees of hypodysplasia. The ureters are wide and tortuous, often with large and laterally placed orifices. Urethral obstruction or atresia may be present in the most severe cases, but usually there is no lower urinary tract obstruction.

Key Points: Hypoplasia and Hypodysplasia

- Hypoplasia and hypodysplasia often are associated with ectopic orifices and sometimes with obstruction.
- Oligomeganephronia is a condition with a reduced number of nephrons and hypertrophy of each nephron.
- Ask-Upmark kidneys have segmented dysplasia, are seen most frequently in association with reflux, and are often the cause of severe hypertension.

Cystic Diseases of the Kidney

The kidney is one of the most common sites in the body for cyst formation. Renal cystic diseases encompass a broad spectrum of sporadic and genetically determined congenital or acquired conditions that have in common the presence of cysts in one or both kidneys. These diseases often require a multidisciplinary approach to evaluation and treatment.

Renal cysts are cavities derived primarily from tubules and are composed of a layer of partially de-differentiated epithelial cells enclosing a cavity filled with urinelike liquid or semisolid material. They may develop in any tubular segment between the Bowman capsule and the tip of the renal papilla, depending on the nature of the underlying disorder. Some cysts are saccular or fusiform structures that resemble diverticula. Other cysts may or may not communicate with a glomerulus, tubule, collecting duct, or calyx, or they may initially have communicated only to become isolated later. **Multicystic dysplasia is an exception in that it arises before formation of the nephron, from abnormal induction of metanephric development, from a primary abnormality of the nephrogenic blastema, or from obstruction occurring early in renal development. Another exception, benign multilocular cyst, represents a neoplastic growth.**

The fundamental processes that are essential for the development and progressive enlargement of renal cysts include (1) proliferation of epithelial cells in segments of renal tubule, (2) accumulation of fluid within the expanding tubule segment, and (3) disturbed organization and metabolism of the extracellular matrix (Fig. 39.6).

FIG. 39.6 Evolution of cysts from renal tubules. Abnormal proliferation of tubule epithelium begins in a single cell after a "second-hit" process disables the function of the normal allele. Repeated cycles of cell proliferation lead to expansion of the tubule wall into a cyst. The cystic epithelium is associated with thickening of the adjacent tubule basement membrane and with an influx of inflammatory cells into the interstitium. The cystic segment eventually separates from the original tubule, and net epithelial fluid secretion contributes to the accumulation of liquid within the cyst cavity. (From Brenner BM, editor: *Brenner and Rector's the kidney,* ed 8, Philadelphia, 2008, Saunders, p 1428.)

An imbalance of the secretory and absorptive properties in proliferating epithelial cells leads to a net accumulation of fluid in otherwise normal renal tubules. Beyond the loop of Henle, tubule cells have the capacity to secrete solutes and fluid on stimulation. This secretory flux operates in competition with the more powerful mechanism by which sodium (Na^+) is absorbed. Under conditions in which Na^+ absorption is diminished, the **net** secretion of sodium chloride (NaCl) and fluid occurs.

Abnormalities of the extracellular matrix in and about renal cysts are seen in all cystic disorders. In the early stages of renal cyst development, changes in expression of collagen I and IV, metalloproteinase activators and inhibitors, integrins, and β-catenin may forecast a vital role for extracellular matrix remodeling in the pathogenesis of renal cysts. A hypomorphic mutation in the mouse laminin α5 gene was found to cause polycystic kidney disease (PKD) (Joly et al., 2006; Shannon et al., 2006).

Until recently, the mechanisms responsible for the abnormal differentiation and functional behavior of the epithelial cells that give rise to the cysts were largely unknown. Evidence now strongly suggests that a long-neglected structure, the primary cilium, is essential in maintaining epithelial cell differentiation. Structural and functional defects in the primary apical cilia of tubular epithelia may have a central role in determining cyst development and the abnormal differentiation and behavior of the cystic epithelium, and in various forms of human and rodent cystic diseases (Torres and Grantham, 2008). There have been several novel signaling pathways identified that are involved in the regulation of these epithelial cells and that are providing new opportunities for targeted therapies to slow and/or prevent cystogenesis (Blanco and Wallace, 2013; Choi et al., 2013; Legué et al., 2019; Ma et al., 2017; Mochizuki et al., 2013; Nikonova et al., 2018; Zhou et al., 2013).

Cystic kidneys of different causes may appear morphologically similar, whereas the same etiologic entity may cause a wide spectrum of renal abnormalities. For example, in ADPKD, tuberous sclerosis, VHL disease, and acquired renal cystic disease (ARCD), the cysts have a hyperplastic lining, sometimes with nodules of hyperplasia or polyps that project into the cyst lumen. However, these hyperplastic conditions are very different from one another. Another example of such similarities is the ectatic collecting ducts seen in two very different clinical entities: autosomal recessive polycystic kidney disease (ARPKD) and medullary sponge kidney.

Classification

In this chapter, the classification of renal cystic disease as outlined in 1987 by the Committee on Classification, Nomenclature, and Terminology of the AAP Section on Urology is used. **The primary distinction is between genetic (inheritable) and nongenetic (nonheritable) disease.** Box 39.1 gives an overview of characteristics associated with the various forms of cystic disease.

Box 39.1

Cystic Diseases of the Kidney

Inheritable

- Autosomal recessive (infantile) polycystic kidney disease
- Autosomal dominant (adult) polycystic kidney disease
  - Juvenile nephronophthisis and medullary cystic disease complex
  - Juvenile nephronophthisis (autosomal recessive)
- Medullary cystic disease (autosomal dominant)
- Congenital nephrosis (familial nephrotic syndrome) (autosomal recessive)
- Familial hypoplastic glomerulocystic disease (autosomal dominant)
- Multiple malformation syndromes with renal cysts (e.g., tuberous sclerosis, von Hippel-Lindau disease)

Nonheritable

- Multicystic kidney (multicystic dysplastic kidney)
- Benign multilocular cyst (cystic nephroma)
- Simple cysts
- Medullary sponge kidney
- Sporadic glomerulocystic kidney disease
- Acquired renal cystic disease
- Calyceal diverticulum (pyelogenic cyst)

The terms *multicystic* and *polycystic* should not be confused, even though both terms literally mean "many cysts." *Multicystic* typically refers to a dysplastic kidney resulting from aberrant renal development. *Polycystic* refers to renal units that developed in a normal fashion, all of which have no dysplasia and have nephrons throughout the kidney. The term *polycystic kidney disease* traditionally is used in reference to two conditions: ARPKD and ADPKD. Many of the PKD entities progress to renal failure as the nephrons become more diseased. In other conditions, such as tuberous sclerosis and VHL disease, there are hyperplastic cysts, and the individual nephrons are normal. Only occasionally do the nephrons become compressed by the cysts or by associated tumors, and only in such situations does renal failure ensue.

Among the nonheritable cystic diseases, benign multilocular cysts, cystic renal cell carcinoma (RCC), and other variants are considered neoplasms. Medullary sponge kidney is a disease principally of dilated ectatic collecting ducts, with cysts playing a lesser role, although the size of the ducts by definition makes them cysts. The nephrons initially are normal.

Inheritable Cystic Disease

Genetic (inheritable) cystic diseases can be classified based on their mode of transmission: autosomal dominant, autosomal recessive, X-linked, and others. Some of these disorders are caused by a single gene defect, some by an X-linked gene defect, and others by chromosomal defects. The modes of inheritance of these diseases and the specific gene or gene locus, where identified, are summarized in Table 39.1.

TABLE 39.1

Characteristics of Major Inheritable and Nonheritable Cystic Kidney Diseases

DISEASE ENTITY	CHROMOSOMAL DEFECT	RENAL FINDINGS	EXTRARENAL MANIFESTATIONS
INHERITABLE			
Autosomal recessive polycystic kidney disease (ARPKD)	Chromosome 6	In newborn usually large, homogeneous, echogenic kidneys	Congenital hepatic fibrosis; biliary dysgenesis
Autosomal dominant polycystic kidney disease (ADPKD)	*PKD1:* chromosome 16 *PKD2:* chromosome 4 *PKD3;* not mapped	Renal cysts scattered throughout parenchyma; large kidneys	Diverticulitis; liver, spleen, pancreatic cysts; mitral valve prolapse; intracranial (berry) aneurysms

Juvenile nephronophthisis and medullary cystic disease complex Juvenile nephronophthisis (autosomal recessive) Medullary cystic disease (autosomal dominant)	Chromosome 2; not mapped	Cysts of corticomedullary junction; develop after onset of renal failure; always thickened tubular basement membrane	Retinitis pigmentosa (16%; also known as Senior-Loken syndrome); rarely skeletal abnormalities, hepatic fibrosis, Bardet-Biedl syndrome, ocular motor apraxia, and other neurologic defects
		Cysts of corticomedullary junction; develop before onset of renal failure; tubular basement membrane may not be thickened	None
Tuberous sclerosis (autosomal dominant)	*TSC1:* chromosome 9 *TSC2:* chromosome 16	Cysts and angiomyolipomas throughout kidney; cysts even present in utero; 3% incidence of RCC	Adenoma sebaceum; epilepsy; mental retardation; cranial tumors
von Hippel-Lindau disease (autosomal dominant)	Chromosome 3	Cysts, adenomas, and clear cell RCC (35%–38% of cases)	Cerebellar hemangioblastomas; retinal angiomas; pheochromocytomas; cysts of pancreas and epididymis
NONHERITABLE			
Multicystic dysplastic kidney	Renal maldevelopment with diffuse cysts and remnants of early metanephros; minimal, if any, nephron development; most		Unusual

	frequent renal cystic disease in newborns		
Benign multilocular cyst	Benign cystic neoplasm of the kidney; remainder of kidney has normal nephrons that may be compromised by growing mass; present more often in males when younger than 4 yr and females when older than 30 yr		None
Simple cysts	Single or multiple cysts; normal nephrons throughout kidney; very common in normal kidneys with increasing age		None
Medullary sponge kidney	Ectatic collecting ducts; nephrons usually normal		None
Acquired renal cystic disease	Diffuse cysts; adenomas; occasionally RCC; increases with duration of ESRD		None

ESRD, End-stage renal disease; *RCC,* renal cell carcinoma.

Autosomal Recessive (Infantile) Polycystic Kidney Disease

ARPKD is typified by relatively rapid, symmetrical, and bilateral enlargement of the kidneys in infants secondary to collecting duct cysts. It is invariably associated with some degree of congenital hepatic fibrosis (Guay-Woodford and Desmond, 2003; MacRae Dell and Avner, 2003; Zerres et al., 1988). ARPKD has been referred to as the "infantile" form in the past; however, the disease can occur in adolescents and young adults, although significantly less frequently. **ARPKD has a spectrum of severity, with the most severe forms appearing earliest in life. If it is not apparent at birth, the disease will become apparent later in childhood (up to age 13 years or, rarely, up to age 20 years).**

The reported incidence of ARPKD varies from 1 in 10,000 to 50,000 live births (Kaplan et al., 1989a; Zerres et al., 1988). However, as many as 50% of affected newborns die in the first few days of life, making for a significantly lower incidence among children who live for at least 1 year. Of those infants who survive the neonatal period, approximately 50% are alive at 10 years of age (Kaplan et al., 1989a).

Genetics

Once the diagnosis of ARPKD is strongly suspected, referral for genetic evaluation and counseling is appropriate. A detailed history should be taken of at least three generations. **Because the disease is transmitted as an autosomal recessive trait, siblings of either sex have a 1 in 4 chance of being affected.**

Despite the clinical variability of ARPKD, it appears that only mutations of a single gene, named *PKHD1* and located on chromosome 6 (6p12), are responsible for the disease. The gene produces a protein called *fibrocystin* (also known as *polyductin*) (Onuchic et al., 2002; Ward et al., 2002). Dysfunction of this protein mediates cystogenesis through dysfunction of the primary cilia of renal epithelial cells. It is highly expressed in the kidney, with levels also present in the liver and pancreas. It is localized to the branching ureteric bud, collecting ducts of the kidney, and biliary ducts, consistent with the phenotype seen in ARPKD, and it is often absent in the patients with ARPKD (Al-Bhalal and Akhtar, 2008; Wilson, 2004).

Clinical Features

Affected children typically have enlarged, echogenic kidneys in utero. Oligohydramnios is common because of the lack of normal urine production by the fetus. The infant often displays Potter facies and deformities of the limbs and may have respiratory distress as a consequence of pulmonary hypoplasia. The affected newborn usually has enormous, kidney-shaped, nonbosselated flank masses that are hard and do not transilluminate. In some cases, the kidneys are large enough to impede delivery. The infant's serum creatinine and BUN begin to rise soon after birth. Of affected individuals 30% to 50% die shortly after birth as a result of uremia or respiratory failure (Capisonda et al., 2003; Guay-Woodford, 2003; Kaplan et al., 1989b). The earlier the age at which the disease is identified, the more severe the disease. **No matter what the severity of the renal disease, all patients with ARPKD have liver involvement in the form of congenital hepatic fibrosis and vary in the degree of biliary ectasia and periportal fibrosis** (Habib and Bois, 1973; Kissane and Smith, 1975).

Patients who survive the neonatal period have a milder form of the disease and are likely to survive into adulthood. Some diagnosed as neonates can live beyond age 3 or 4 years before going into renal failure (Avni et al., 2002; Cole et al., 1987). **Hypertension and renal insufficiency are the major manifestations in surviving children, with liver disease becoming more prevalent in older patients.** The exact cause of hypertension remains unclear. Consequences of chronic renal insufficiency (e.g., growth failure, anemia, osteodystrophy) become more apparent as the children age. Renal calcifications occur commonly in patients with ARPKD.

Patients whose disease appears later in life develop renal failure and hypertension more slowly. In general, their clinical problems are the consequence of liver disease rather than the renal disease, with hepatic fibrosis leading to portal hypertension, esophageal varices, and hepatosplenomegaly. Hepatocellular function is rarely abnormal, with liver enzymes typically remaining normal. The kidneys in these patients are often normal in appearance.

No association of ARPKD with renal neoplasms has been reported.

Histopathology

The kidneys are symmetrically enlarged (up to 20 times their normal size) and retain a reniform configuration. The parenchyma exhibits small subcapsular cysts, representing generalized fusiform dilations of the collecting tubules radiating from the medulla to the cortex with their long axis perpendicular to the renal surface (Bisceglia et al., 2006). Almost 100% of collecting ducts are affected in the most severe cases. The cortex is crowded with minute cysts (Fig. 39.7A). The renal pedicle is normal, as are the renal pelvis and ureter.

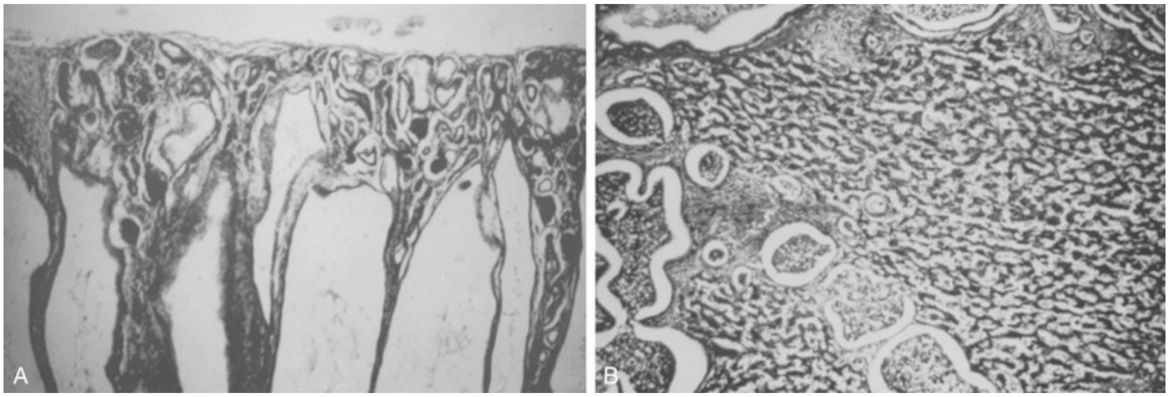

FIG. 39.7 Newborn with abdominal mass and pulmonary hypoplasia. Neither parent had a history of renal cysts. (A) Renal histology demonstrates dilated ducts radiating out to the periphery of the kidney. (B) On liver histology, ectatic biliary ducts are seen in the left half of the figure, and periportal fibrosis is seen at the upper edge. These findings confirm the diagnosis of autosomal recessive polycystic disease.

ARPKD affects the kidneys and the liver in approximately inverse proportions (Torres and Grantham, 2008). The disease may be viewed as a spectrum ranging from severe renal disease and mild liver changes at one extreme to mild renal damage and severe liver disease at the other. The form with severe renal disease is the most common and the one typically seen at or near the time of birth. The form with less severe renal disease and more significant liver damage is present in older children. **All children with ARPKD have lesions in the periportal areas of the liver** (Fig. 39.7B; Habib and Bois, 1973; Kissane and Smith, 1975).

Evaluation

The diagnosis may be suspected from in utero ultrasound examination and may be associated with oligohydramnios, a finding secondary to low urinary output. **In fetus and newborn, ultrasonography identifies bilateral, very enlarged, diffusely echogenic kidneys, especially when compared with the echogenicity of the liver** (Fig. 39.8A)**. The increased echogenicity is due to the presence of**

numerous microcysts (created by tightly compacted, dilated collecting ducts) that result in innumerable interfaces. Compared with normal newborn kidneys, in ARPKD, the pyramids are hyperechogenic because they blend in with the rest of the kidney, and the kidneys typically have a homogeneous appearance (see Fig. 39.8A). In ADPKD, the cysts, if apparent in newborns, are usually diffuse and large (see Fig. 39.8B). Also included in the differential diagnosis are severe bilateral hydronephrosis (the kidneys are enlarged with hypoechogenic calyces), multicystic kidney (hypoechogenic cysts lie within a nonreniform mass that has very little parenchyma), sporadic glomerulocystic kidney disease (GCKD), bilateral mesoblastic nephroma, Wilms tumor, and bilateral renal vein thrombosis. If the diagnosis is in doubt, CT is valuable because it is more sensitive to inhomogeneity (and therefore to tumor) within abdominal masses.

FIG. 39.8 Ultrasonographic appearance of the kidneys in neonates with autosomal recessive polycystic kidney disease (ARPKD) and autosomal dominant polycystic kidney disease (ADPKD) can be similar. (A1 and A2) Newborn with ARPKD. Note the large size and hyperechogenic,

homogeneous appearance of the renal parenchyma. A2 is a cross-sectional cut of the baby's abdomen showing both kidneys to be large and occupying a large portion of the abdominal cavity. (B1 and B2) Newborn with ADPKD. Again note the abnormal renal architecture and the hyperechogenic appearance of the kidneys. The parenchyma consists of multiple tiny cysts, with some being slightly larger than others. (Courtesy Marta Hernanz-Schulman, MD.)

Considerable overlap in clinical presentation and imaging findings can occur between ADPKD and ARPKD. Occasionally, a newborn with severe ADPKD can also have enlarged, homogeneously hyperechogenic kidneys. Age at onset can overlap, and typically, when ADPKD manifests at birth, cysts are apparent on the sonographic image. Macrocysts are rare in newborns with ARPKD but do increase in frequency as the child gets older, sometimes producing an appearance similar to that of the dominant disease. Cysts less than 1 cm appear more often than large cysts (Fig. 39.9; Avni et al., 2002). Hepatic fibrosis can rarely occur in patients with ADPKD, as can brain aneurysms with ARPKD (Cobben et al., 1990; Neumann et al., 1999). The correct diagnosis of ARPKD depends on the overall clinical data: a positive family history with a recessive mode of inheritance, a positive liver biopsy, and the lack of the extrarenal malformations often associated with other renal cystic diseases.

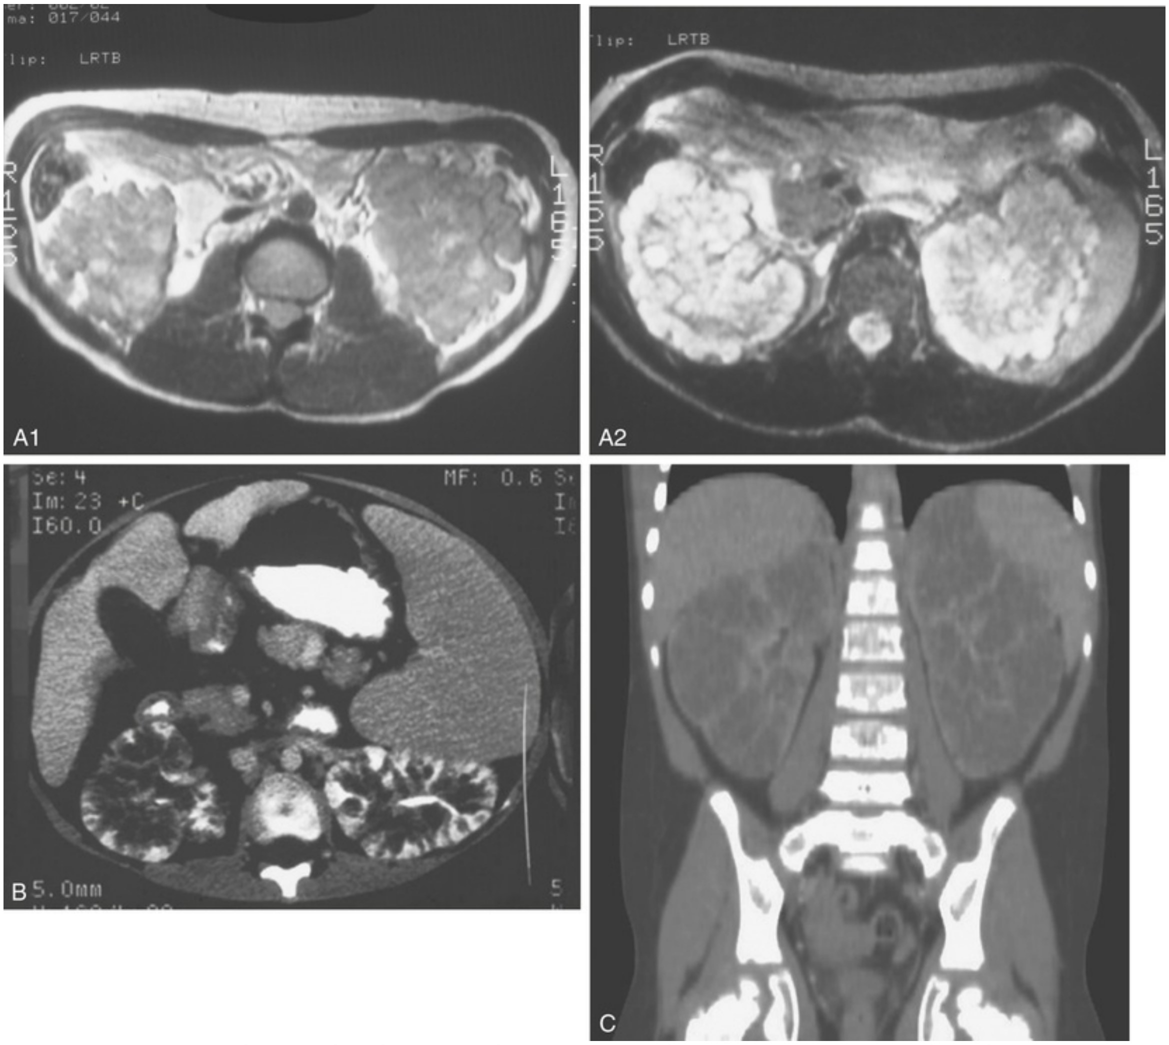

FIG. 39.9 (A1 and A2) Magnetic resonance images of an 8-month-old child with autosomal recessive polycystic kidney disease (ARPKD) demonstrating multiple renal cysts. (A1) On T1-weighted image, fluid content of cysts appears dark. (A2) On T2-weighted image, the fluid content appears white. (B) Computed tomography scan of a child with ARPKD. Horizontal cuts showing contrast puddling in collecting ducts. (C) Coronal cut. Note that the kidneys are enlarged and the enhancing renal parenchyma is effaced by nonenhancing cysts and represents the progression and normal history of the disorder. (A, Courtesy Walter Berdon, MD; B, courtesy Marta Hernanz-Schulman, MD.)

Treatment

No cure has been found for ARPKD. Respiratory care can ease or extend the child's life. Severely affected neonates may require unilateral or bilateral nephrectomy, because of respiratory and nutritional compromise. Patients who survive may require treatment for hypertension, congestive heart failure, and renal and hepatic failure. Portal hypertension may be dealt with by decompressive procedures such as a splenorenal shunt. Esophageal varices may be managed, at least temporarily, by gastric section and reanastomosis. Endoscopic sclerotherapy is widely used in pediatric and adult patients with bleeding varices. Hemodialysis and renal transplantation must eventually be considered in many patients. Often, nephrectomy is required before peritoneal dialysis to make room in the intra-abdominal cavity for dialysate.

Key Points: Autosomal Recessive Polycystic Kidney Disease

- ARPKD is secondary to a mutation of the *PKHD1* gene on chromosome 6.
- The severe form manifests in utero or in infancy; milder cases can manifest later in childhood and rarely up to age 20.
- All affected individuals have some degree of congenital hepatic fibrosis.
- When it manifests early, it is associated most often with very large kidneys that are homogeneously hyperechogenic.
- Discrete cysts appear more often as the child gets older.
- RUS reveals bilateral, very enlarged, diffusely echogenic kidneys, and the increased echogenicity is a result of the presence of numerous microcysts (created by tightly compacted, dilated collecting ducts) that result in innumerable interfaces.
- Considerable overlap in clinical presentation and imaging findings can occur between ADPKD and ARPKD.

Autosomal Dominant (Adult) Polycystic Kidney Disease

ADPKD is by far the most common inheritable form of renal cystic disease, with an incidence of approximately 1 in 400 to 1000 live births (Grantham, 1996; Iglesias et al., 1983). It is an important cause of renal failure, accounting for 7% to 15% of patients who receive hemodialysis (Grantham, 1996; Hildebrandt, 1995; Wilson, 2004). The trait theoretically has a 100% penetrance, and, on average, because it is transmitted in an autosomal dominant fashion, 50% of an affected individual's offspring will likewise be affected. Although a positive family history is one of the major criteria for the diagnosis of ADPKD, 10% of cases occur sporadically. Of affected persons, 96% will manifest the disease clinically by age 90 years (Gabow, 1991).

Although most cases are identified between the fourth and fifth decades of life, the condition has been reported in newborns and infants (Proesmans et al., 1982). All affected individuals manifest the disease (although not necessarily symptomatically) if they live long enough, but renal failure is seldom seen before the age of 40 years, unless the disease manifests during infancy, in which case it is much more aggressive.

A number of associated anomalies are common, including cysts of the liver, pancreas, spleen, and lungs; aneurysms of the circle of Willis (berry aneurysms); colonic diverticula; aortic aneurysms; and mitral valve prolapse (Table 39.2).

TABLE 39.2

Comparison of Autosomal Recessive and Autosomal Dominant Polycystic Kidney Disease

	AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE	AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE
Gene defect	Chromosome 6	Chromosomes 4 and 16
Incidence	1 : 5000–40,000	1 : 500–1100
Usual age at clinical presentation	Perinatal	Third to fifth decades

Typical ultrasonographic appearance of kidneys	Symmetrically enlarged, homogeneous, hyperechogenic	Large, cystic kidneys, sometimes asymmetrical
Histology	Collecting duct ectasia; cysts derived principally from collecting duct	Microcysts and macrocysts derived from the entire nephron
Liver	Always with congenital hepatic fibrosis but of varying severity	Cysts, mostly in adults
Other organ system(s) involvement	None	Intracranial (berry) aneurysms, colonic diverticuli; mitral valve prolapse; cysts of other organs (seminal vesicle, arachnoid membrane, pancreas)

Genetics

There are two major genetic forms of ADPKD caused by mutation in the genes *PKD1* and *PKD2* (Breuning et al., 1987; Pieke et al., 1989; Reeders et al., 1985; Ryynanen et al., 1987). *PKD1* has been localized to the short arm of chromosome 16, with its gene product being polycystin-1. Mutations in the *PKD1* gene account for 85% of ADPKD cases. These patients typically have a more rapidly progressive form of the disease, with cysts usually developing by the age of 20 years (64% of children have cysts by the age of 10 years and 90% by the age of 20 years) and ESRD occurring in their 50s (Chakraborty and McHugh, 2005). The *PKD2* gene has been mapped to the long arm of chromosome 4 and it encodes the protein polycystin-2. *PKD2* mutations account for about 15% of ADPKD cases, and in these patients, the disease progresses more slowly. ESRD usually does not occur until these patients are in their 70s (Hateboer et al., 1999). The presence of a third locus *(PKD3)* is now accepted as the cause of disease in a very small percentage of patients who have been found to have neither a *PKD1* nor a *PKD2* gene defect (Dauost et al., 1993). **When either the *PKD1* or the *PKD2* gene is abnormal, cystic kidneys can develop.** Because defects of *PKD1* and *PKD2* manifest similarly, it has been suggested that the gene product of each is involved in the same pathway and that an abnormality of either product results in similar manifestations of the disease (Qian et al., 1996).

Every cell of the nephron and collecting duct has the *PKD1* or *PKD2* mutation; however, only 1% to 2% of these glomerular units are affected by cyst formation. Only those nephrons that undergo a disruption of a second allele undergo cystic enlargement. This is the “second hit” of the Knudson theory, which has been proposed to explain the focal nature of the cysts (Knudson, 1971). In this model, a mutated *PKD1* (or *PKD2*) gene is inherited from one parent, and a wild-type gene is inherited from the unaffected parent. During the lifetime of the individual, the wild-type gene undergoes a somatic mutation and becomes inactivated. Loss of heterozygosity caused by somatic mutations of the *PKD1* and *PKD2* genes has been identified in the cells lining the cysts in the kidney and liver (Qian et al., 1996; Watnick et al., 1998). The phenomenon of genetic anticipation is seen as well; it manifests with progressively earlier presentation and increased severity in subsequent generations of patients with ADPKD (Fick et al., 1994; Zerres et al., 1994). Genetic testing for *PKD1* and *PKD2* is commercially available through polymerase chain reaction amplification and direct DNA sequencing.

Occasionally, the classic ADPKD phenotype is seen in conjunction with tuberous sclerosis. This association is a classic example of a “contiguous gene syndrome,” which is a disorder caused by deletion of multiple gene loci that are adjacent to one another. Contiguous gene syndromes are characterized by multiple, apparently unrelated, clinical features caused by deletion of the multiple adjacent genes. Because of the fact that the *PKD1* gene is immediately adjacent to the *TSC2* gene (the most important gene in tuberous sclerosis) on chromosome 16, large deletions in this area can involve the *PKD1* and *TSC2* genes. Thus these patients have the classic features of tuberous sclerosis in addition to the renal cystic phenotype of ADPKD (Galliani et al., 2015; Murakami et al., 2012; Rito et al., 2017).

Pathogenesis

The *PKD1* and *PKD2* proteins, polycystin-1 (PC1) and polycystin-2 (PC2), are transmembrane proteins that in all likelihood form a functional complex. When working properly, PC1 and PC2 inhibit cell proliferation by several pathways. Polycystin-1 functions as a mechanoreceptor located on the primary cilium of renal tubular cells. These cilia project from the surface of the cell into the lumen of the ducts and tubules. Mutations that block the assembly of these cilia are known to cause many cystic diseases of the kidney. The products of the *ADPKD,* *ARPKD*, and nephronophthisis (NPH) genes are at least partially localized to these primary cilia. Polycystin-1 is linked to polycystin-2, which contains a calcium (Ca^{2+}) channel. When the mechanoreceptor of PC1 is stimulated by calcium-containing urine flowing through the tubule, the calcium channel of PC2 opens and calcium enters the cell (Braun, 2009; Nauli et al., 2003). This process regulates the proliferative state of the renal tubular cells through a variety of signaling pathways (e.g., cAMP, extracellularly regulated kinase [ERK], mammalian target of rapamycin [mTOR]). The cilia likely serve as organization centers for this signal transduction (Pazour, 2004).

In ADPKD, the polycystins do not function properly, and these proliferative pathways are unopposed and cyst formation occurs to varying degrees.

Increased levels of cAMP have been noted in multiple animal models of ADPKD, and biochemical processes that alter cAMP appear to affect the presence and size of renal cysts. For example, cAMP is broken down by phosphodiesterases. Caffeine and methylxanthine products, such as theophylline, interfere with phosphodiesterase activity, raise cAMP in epithelial cell cultures from patients with ADPKD, and increase cyst formation in canine kidney cell cultures (Belibi et al., 2002; Mangoo-Karim et al., 1989). The abnormal response to cAMP is directly linked to alterations in Ca^{2+} channel activity and results in the abnormal response of cyst-derived cells. This has also been shown to be regulated by cAMP stimulation of the mitogen-activated protein kinase/extracellularly regulated kinase (MAPK/ERK) signaling pathways, which leads to abnormal cellular proliferation of the PKD renal epithelial cells.

Upregulation of the vasopressin V_2 receptor (VPV2R) has also been shown to increase cAMP levels. In genetically produced polycystic animals, two antagonists of the vasopressin V_2 receptor (VPV2R), OPC31260 and OPC41061 (tolvaptan), decreased cAMP and ERK, prevented or reduced renal cysts, and preserved renal function (Gattone et al., 2003; Wang et al., 2005). Not surprisingly, simply increasing water intake decreases vasopressin production and the development of PKD in rats (Nagao et al., 2006). Polycystic kidney (PCK) animals with no vasopressin activity had virtually no cAMP or renal cysts, whereas animals with increasing amounts of vasopressin had progressively larger kidneys with more numerous cysts. Administration of synthetic vasopressin to PCK rats that totally lacked vasopressin re-created the full cystic disease (Braun, 2009; Wang et al., 2008). Finally, the absence of polycystin permits excessive kinase activity in the mTOR pathway and the development of renal cysts (Shillingford et al., 2006). The mTOR system can be blocked by rapamycin, which has been shown to slow PKD progression in rats (Wahl et al., 2006).

Clinical Features

Phenotypes associated with ADPKD are highly variable in penetrance. This variability related to the severity of renal disease can range from fetal demise and neonatal death to adequate renal function into old age. Characteristics of the associated liver disease and extrarenal manifestations can also be variable. *PKD1* and *PKD2* gene mutations are obviously critical, but intrafamilial variability also indicates that genetic background and environmental factors can also affect ultimate clinical expression of the disease (Rossetti and Harris, 2007). Now that the families of ADPKD patients are being screened by ultrasonography, large numbers of asymptomatic children with renal cysts are being identified before full-blown disease develops. Bilateral renal involvement is the usual presentation, but 17% of cases are asynchronous or asymmetrical, especially in children. These extreme forms of asymmetry are referred to as *unilateral ADPKD*, with the involvement in the contralateral kidney becoming apparent at a much older age (Bisceglia et al., 2006; Strand et al., 1989).

Typically, signs or symptoms first occur between the ages of 30 and 50 years (Glassberg et al., 1981). These include microscopic and gross hematuria, flank pain, gastrointestinal symptoms (perhaps secondary to renomegaly or associated colonic diverticula), renal colic (secondary either to clots or stones), and hypertension. Microscopic or gross hematuria is seen in 50% of patients, and in 19% to 35% it is the presenting sign (Delaney et al., 1985; Gabow et al., 1992; Milutinovic et al., 1984; Zeier et al., 1988). Because patients with ADPKD have increased renal mass, erythropoietin levels are increased, making anemia unusual even when ESRD is present (Gabow, 1993).

Pain (flank and/or abdominal) is the most common presenting symptom in adults. This results from a number of possible factors: mass effect (cysts impinging on abdominal wall or neighboring organs), bleeding into the cysts, urinary tract infection (including infected cysts), and nephrolithiasis. Twenty percent to 30% of patients with ADPKD develop stones (Fick et al., 1994), and these are treated by conservative means if possible (i.e., urine alkalinization, spontaneous stone passage, extracorporeal shock wave lithotripsy). Uric acid stones and calcium oxalate stones are equally prevalent. The finding of hydronephrosis, which helps make the diagnosis of stones, may not be as useful in ADPKD patients because of the number of cysts camouflaging the findings (Choyke et al., 1995). Urinary tract infections are more frequent in female patients. Cyst aspiration for diagnostic and therapeutic reasons should be considered in the setting of suspected cyst infection.

As BP screening has become more widespread, hypertension has become a very common form of presentation (Zeier et al., 1988). Hypertension is present in roughly 50% of patients 20 to 35 years old having ADPKD with normal renal function. Almost 100% of patients with ESRD have hypertension (Kelleher et al., 2004). The hypertension seems to be renin mediated, secondary to stretching of the intrarenal vessels around cysts, causing distal ischemia (Gabow, 1993). Diagnosis and treatment of this hypertension are critical to slow the progression of renal failure and to decrease morbidity and mortality from heart disease and cerebral aneurysms.

The development of renal failure is highly variable. Renal function is usually maintained, despite increasingly rapid cyst growth, until the fourth to sixth decade of life. Risk factors for earlier onset of ESRD include *PKD1* gene mutation, male gender, first episode of hematuria before age 30 years, onset of hypertension before age 35 years, hyperlipidemia, and sickle cell trait (Johnson and Gabow, 1997; Yium et al., 1994). There is a strong relationship between the decline in renal function and the size of the kidneys and cyst volumes. As the cysts, and thus the kidneys, become larger, renal function declines proportionately (Gabow et al., 1990a). Hypertension and vascular remodeling secondary to cyst expansion also contribute to progressive renal failure.

Extrarenal Manifestations

Hepatic cysts, usually identified incidentally by ultrasonography, are the most common extrarenal manifestation of ADPKD. These cysts are associated with PKD1 and non-PKD1 genotypes. They are rare in children, and their frequency increases with age. They are present in almost all ADPKD patients by the age of 50 years (Bae et al., 2006). Hepatic cysts are more prevalent and their size greater in females (Fick et al., 1994). Several studies have shown an estrogen effect on hepatic cyst growth (Gabow et al., 1990b; Sherstha et al., 1997). Hepatic cysts are usually asymptomatic but can occasionally cause symptoms because of mass effect, complicating infection, or hemorrhage. In rare instances, enlargement of hepatic cysts leads to portal hypertension and bleeding esophageal varices (Campbell et al., 1958). When secondary portal hypertension appears, differentiating ADPKD from ARPKD can be difficult. In ARPKD, portal hypertension is seen much more frequently and is always secondary to congenital hepatic fibrosis. However, congenital hepatic fibrosis, on very rare occasions, may accompany ADPKD as well, particularly when the diagnosis is made perinatally.

Intracranial aneurysms (ICAs)—predominantly aneurysms of the circle of Willis (berry aneurysm)—occur in 10% to 30% of patients, and approximately 9% of these patients die because of subarachnoid hemorrhages (Grantham, 1979; Hartnett and Bennett, 1976; Ryu, 1990; Sedman and Gabow, 1984; Wakabayashi et al., 1983). The most common symptom of subarachnoid hemorrhage is the sudden onset of a severe headache, frequently associated with nausea and vomiting. When this occurs, immediate medical evaluation is obviously imperative. Morbidity and mortality from these aneurysms are strongly influenced by positive family history and the *PKD1* genotype. Now, with MRI, even small berry aneurysms can be detected. These aneurysms, when diagnosed, average only 6.1 mm. Although small aneurysms (1 cm) have a lower risk of rupture, patients with small aneurysms have a greater risk of rupture when there is a positive family history of ruptured ICAs or the presence of ADPKD (Huston et al., 1993). Control of hypertension is critical to minimize the risk of aneurysm rupture. In some patients with ADPKD, hemorrhage follows the rupture of *intracerebral* arteries, which is the usual type of intracranial hemorrhage seen in patients with hypertension who do not have ADPKD.

Cysts may also occur in the seminal vesicles (40%), arachnoid membrane (8%), and pancreas (5%). Seminal vesicle cysts rarely cause infertility; however, many of these men may have problems with sperm motility. Arachnoid membrane and pancreatic cysts are typically asymptomatic. Other abnormalities associated with ADPKD are mitral valve prolapse and colonic diverticulosis (Hossack et al., 1986; Kupin et al., 1987; Scheff et al., 1980). Patients who have diverticulosis are more likely to have hepatic cysts and symptomatic berry aneurysms (Kupin et al., 1987).

Association With Renal Cell Carcinoma

The incidence of renal adenomas is almost as high in ADPKD as in ARCD associated with ESRD (i.e., one in four to five patients). However, whereas ESRD is associated with an increased incidence of RCC, especially when associated with ARCD (three to six times the incidence seen in the general population), **the incidence of RCC in patients with ADPKD is no higher than that in the general population.** However, there are certain findings considered typical of a predisposition to RCC that are seen more frequently in patients with ADPKD than in the general population. For example, RCC in ADPKD is often diagnosed at a younger age, is more often concurrently bilateral (12% vs. 1% to 5% in the general population), multicentric (28% vs. 6%), and sarcomatoid (33% vs. 1% to 5%) (Keith et al., 1994). The diagnosis of RCC in the context of ADPKD can be difficult, because tumor may be masked by the complex cystic appearance of the kidney. In addition, cystic hemorrhage, degenerating blood clots, proteinaceous debris, and infection can also complicate the diagnosis.

Histopathology

ADPKD kidneys typically maintain their reniform shape, and their size can range from minimally enlarged in early disease to massive enlargement in more advanced disease. Both kidneys are usually equally affected, and the cysts range from a few millimeters to a few centimeters in diameter and appear diffusely throughout the cortex and medulla with communications at various points along the nephron (Kissane, 1974). The cysts appear to begin as focal tubular outpouchings, and as they enlarge they usually become detached from their tubule of origin. The first pathological finding in fetuses is focal tubular dilation, which may occur anywhere along the nephron (Fig. 39.10; Choyke et al., 1995).

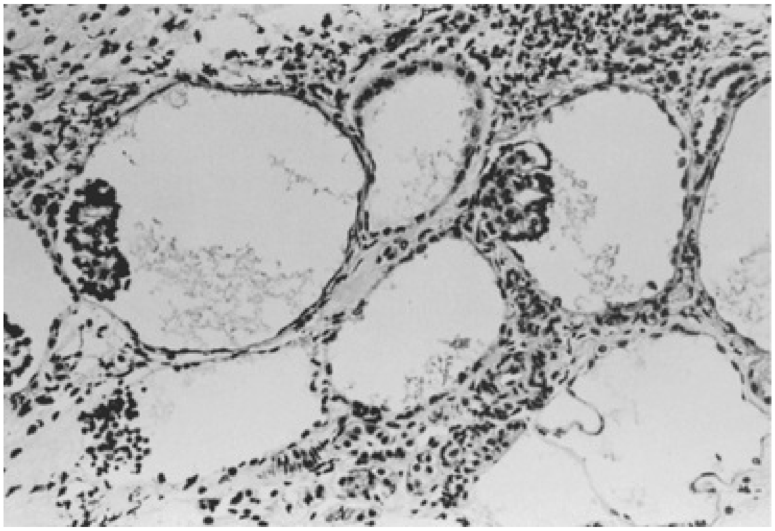

FIG. 39.10 Glomerular cysts with a pattern compatible with autosomal

dominant polycystic kidney disease in early childhood (190×). (From Bernstein J, Gardner KD Jr: Cystic disease and dysplasia of the kidneys. In Murphy WM, editor: *Urological pathology,* Philadelphia, 1989, Saunders, pp 483–524.)

Epithelial hyperplasia or even adenoma formation in the cyst wall is common, and the basement membrane of the wall is thickened. Arteriosclerosis is present in more than 70% of patients with preterminal or terminal renal failure, and interstitial fibrosis, with or without infiltrates, is common (Zeier et al., 1988). This fibrosis may be secondary to infection or to an inflammatory reaction set off by spontaneously rupturing cysts.

Up to 90% of adults with ADPKD have cysts of the liver (Bae et al., 2006). These cysts are lined by a single layer of epithelium resembling that of the biliary tract and contain fluid that resembles the bile salt–independent fraction of the bile.

Evaluation

To make the diagnosis, it is important to have at least three generations of the patient's family history. Questions should be asked about renal disease, hypertension, and strokes. Patients and families should be counseled before any imaging or other testing is undertaken. Genetic testing can be used when the imaging results are equivocal and when a definite diagnosis is required. Benefits of testing include making a diagnosis that may affect family planning, early detection and treatment of disease complications, and selection of genetically unaffected family members for living donor–related renal transplantation. Disadvantages to testing include discrimination in terms of insurability and employment associated with a positive diagnosis, as well as the psychological stress of impending organ failure.

Abdominal ultrasonography may reveal renal cysts (Fig. 39.11) as well as cysts in other organs. **Ultrasonographic diagnostic criteria for individuals at 50% risk for the disease include at least two unilateral or bilateral cysts in individuals younger than 30 years of age, two cysts in each kidney in individuals 30 to 59 years of age, and four cysts in each kidney in individuals 60 years of age or older** (Ravine et al., 1994). The sensitivity of these criteria is nearly 100% for individuals 30 years or older and for younger individuals with *PKD1* mutations but only 67% for individuals with *PKD2* mutations younger than 30 years (Nicolau et al., 1999). When there is no family history to support a diagnosis of ADPKD, a presumptive diagnosis can be made if bilateral renal cysts are present and two or more of the following symptoms are present as well: bilateral renal enlargement, three or more hepatic cysts, cerebral artery aneurysm, and a solitary cyst of the arachnoid, pineal gland, pancreas, or spleen (Grantham, 1993).

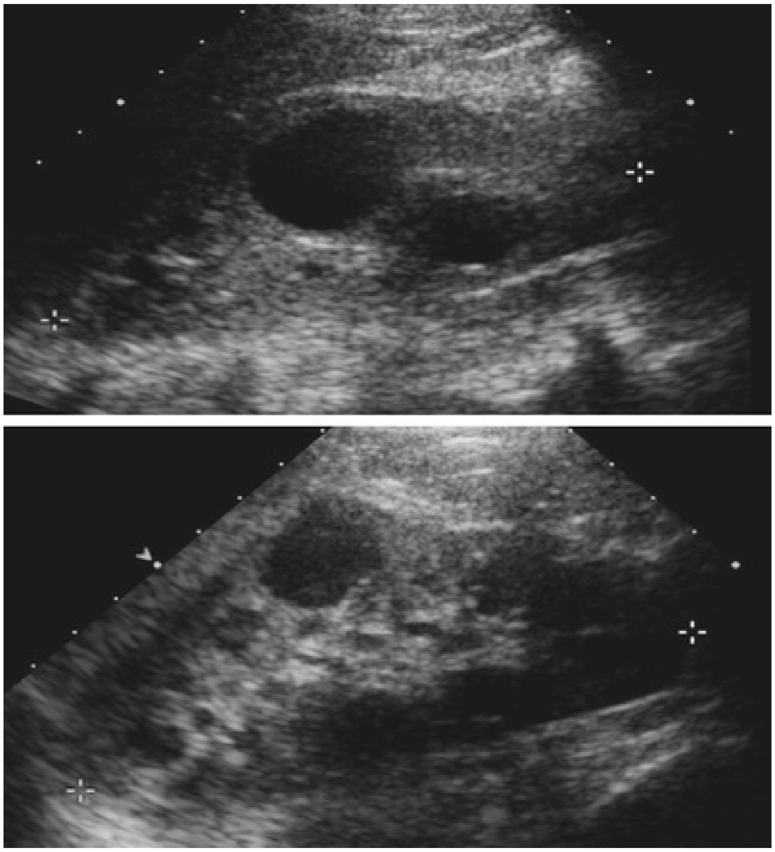

FIG. 39.11 Renal ultrasonogram of 20-year-old patient newly diagnosed with autosomal dominant polycystic kidney disease. Note the presence of multiple cysts in both kidneys. (Courtesy Marta Hernanz-Schulman, MD.)

CT or MRI (or both) may be helpful in some cases and often are superior to ultrasonography for detecting cysts in organs other than the kidney (Fig. 39.12A). CT is helpful in making the diagnosis of hemorrhage within a cyst. More acute hemorrhage has a higher density (50 to 90 Hounsfield units [HU]) than old hemorrhage (Choyke et al., 1995). MRI also may be helpful, particularly in patients with compromised renal function, because no contrast agent is needed (Fig. 39.12B).

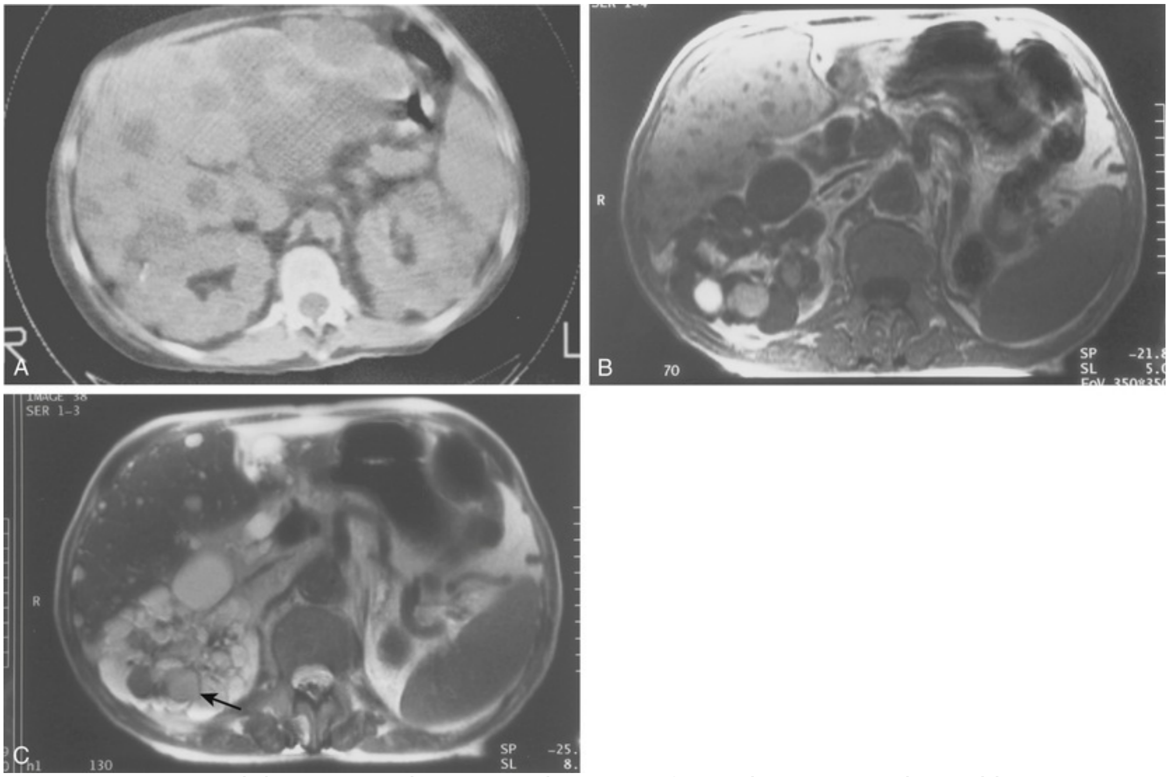

FIG. 39.12 (A) Computed tomography scan of an adult male patient with autosomal dominant polycystic kidney disease (ADPKD). Bilateral renal cysts are seen in enlarged kidneys with calcification. Large asymptomatic cysts are seen throughout the liver as well. (B and C) A 55-year-old woman with ADPKD. Patient has had a left nephrectomy for pain. Right renal and hepatic cysts are seen on both T1- and T2-weighted coronal images. (B) T1-weighted image demonstrates renal cysts with low and high (white) signals. High-signal cysts correlate with intracystic hemorrhage. (C) On T2 weighting, hemorrhagic cysts are dark, and cysts without hemorrhage are white. On T2 weighting with the patient in the supine position, cysts with blood tend to get darker more posteriorly *(arrow).* (Courtesy H. Zinn, MD.)

When ADPKD manifests in utero or in infancy, 50% of affected kidneys are large with identifiable macrocysts (Pretorius et al., 1987). However, the kidneys may appear identical to those seen in ARPKD, having no apparent macrocysts and showing only enlargement and homogeneous hyperechoic features. In such situations, clinicians must look for a parent with ADPKD.

Treatment and Prognosis

Current therapy is directed toward lessening the complications of ADPKD and delaying the onset of ESRD. There is no known cure at this time. More than 60% of patients with ADPKD who do not yet have renal impairment

have hypertension (Gabow et al., 1984), which can worsen renal function, cause cardiac disease, and predispose the patient to intracranial hemorrhage. **The complications of ADPKD can be reduced significantly by controlling hypertension.** There is no proven antihypertensive agent of choice; however, ACE inhibitors or angiotensin receptor antagonists would seem to be logical first-line choices. Not only does the hypertension associated with ADPKD appear to be renin mediated, but these drugs increase renal blood flow, have minimal side effects, and may have renoprotective properties beyond BP control. The optimum BP target is not clear. Ongoing studies will determine whether a low BP target is more protective of renal function than a standard BP target (<130/80 mm Hg) and whether combination drug therapy is more advantageous than single-drug therapy.

Chronic pain must be evaluated and entities such as infection, stone, and tumor treated accordingly. The use of chronic nephrotoxic analgesics (nonsteroidal anti-inflammatory drugs [NSAIDs]) must be avoided. The use of narcotic analgesics should be limited to acute pain episodes, because patient dependence on narcotics is a significant risk in this patient population. When conservative measures fail, surgical management must be considered. Ultrasonography- or CT-guided cyst aspiration is a straightforward procedure and may be diagnostic and therapeutic. Surgical unroofing of multiple or very large cysts can potentially alleviate symptoms of pain and can be performed either laparoscopically or through open flank or dorsal lumbotomy incisions (Elzinga et al., 1992; Lee and Clayman, 2004; Lee and Lee, 2003). The effect of laparoscopic unroofing in those patients with hypertension was variable. Surgical intervention appears only to improve symptoms and does not appear to either accelerate the decline of renal function or preserve declining renal function. Nephrectomy is indicated for symptomatic patients with ESRD.

Upper urinary tract infections are common in patients with ADPKD, especially women, and must be treated appropriately. If a patient with suspected pyelonephritis does not respond to an appropriate antibiotic, clinicians must consider whether the infection may be present in a noncommunicating cyst (Gabow, 1993). Actual cyst infections can be challenging to treat because of poor cyst penetration of many antibiotics. Lipophilic antibiotics, such as trimethoprim-sulfamethoxazole, chloramphenicol, and fluoroquinolones, are the best choices (Bennett et al., 1990; Schwab et al., 1987). If appropriate antibiotic therapy fails, percutaneous or surgical drainage of infected cysts may be required. Complicating factors, such as urinary tract obstruction, renal or perinephric abscess, or urolithiasis, must be excluded.

Screening for asymptomatic berry aneurysms is not currently recommended unless the patient has a family history of aneurysm or subarachnoid hemorrhage, previous aneurysm rupture, need for screening in preparation for major elective surgery, high-risk occupation (e.g., airline pilot), or a high anxiety level over the possibility of ICA (Pirson et al., 2002). CT and magnetic resonance angiography are the imaging studies of choice, although the former requires intravenous contrast. Aneurysm rupture occurs most often in people with larger aneurysms and/or poorly controlled high BP. Screening of low-risk patients is not recommended because aneurysms are rare in this group, and most aneurysms that are found have a low risk of rupture. Conservative management is usually recommended for ADPKD patients with small (<7 mm) aneurysms detected by presymptomatic screening. Aneurysms that are larger than 7 to 10 mm have a higher risk of rupture (up to 2% per year for larger aneurysms). Cerebral aneurysms of this size and those that cause symptoms may be corrected with open surgical clipping or with endovascular procedures, placing a coil within the aneurysm. Smaller aneurysms that do not cause symptoms are much less likely to rupture and are not routinely corrected, except in patients with a history of a bleeding aneurysm.

Emerging Therapeutics

Changing the natural course of the disease by altering the course of cyst growth has received the most attention in recent years. The HALT PKD study is the largest treatment study ever performed on patients with PKD, and the National Institutes of Health (NIH) extended the study because of the valuable information being obtained. This study examined the role of BP control versus the impact of specific medications on the course of the disease and assessed whether combination ACE inhibitor (lisinopril) and angiotensin receptor blocker (ARB; telmisartan) therapy is more effective in slowing cyst progression than ACE inhibition alone. The study was completed in June 2014, and in a recent report by Schrier et al. (2014) showed that in early ADPKD, the combination of lisinopril and telmisartan did not significantly alter the rate of increase in total kidney volume. As compared with standard blood-pressure control (120–130/70–80), rigorous blood-pressure control (95–110/60–75) was associated with a slower increase in total kidney volume, no overall change in the estimated GFR, a greater decline in the left-ventricular-mass index, and greater reduction in urinary albumin excretion (Schrier et al., 2014). From this study, the investigators also hope to learn how to predict when renal insufficiency will occur in individual patients (Steinman, 2011).

Approaches have also been undertaken to reduce the levels of cAMP in the kidneys of ADPKD patients. A recent phase III trial showed that compared with placebo, tolvaptan, a selective vasopressin V_2-receptor antagonist, slowed the increase in total kidney volume and the decline in renal function over a 3-year period in these patients. It was, however, associated with a relatively high discontinuation rate as a result of adverse events, such as increased aquaresis (thirst, polyuria, nocturia, and polydipsia as a result of the excretion of electrolyte-free water) and liver function abnormalities. Serious adverse events associated with chest pain and headache were also slightly more frequent in the tolvaptan group.

Somatostatin, known to inhibit vasopressin-induced cAMP, has also been tested in humans and has shown substantial retardation of the increase in kidney volume (Chapman, 2007). Two studies have evaluated the efficacy of blocking mTOR with rapamycin and have shown a significant reduction in kidney cyst burden (Tao et al., 2005; Wahl et al., 2006). Other drugs shown to be effective in preclinical trials and of potential value for the treatment of human PKD include ErbB1 (epidermal growth factor receptor) and ErbB2 tyrosine kinase inhibitors, Src kinase inhibitors, MEK inhibitors, and cyclin-dependent kinase inhibitors. These drugs, which have been developed for the treatment of neoplastic diseases, may also be considered for the treatment of PKD (Brenner, 2008; Bukanov et al., 2006; Omori et al., 2006; Sweeney et al., 2000; Wilson et al., 2006).

Key Points: Autosomal Dominant Polycystic Kidney Disease

- ADPKD is the most common inheritable form of renal cystic disease.
- ADPKD most often becomes clinically apparent after age 30 years but may manifest at any age, including in utero.
- Ninety-nine percent of affected individuals have a mutation either of the *PKD1* gene on chromosome 16 or, less often, of the *PKD2* gene on chromosome 4.

- The protein products of *PKD1* and *PKD2* are PC1 and PC2, and they inhibit cell proliferation through several pathways.
- Cysts can be identified sonographically before age 20 years in almost all affected individuals.
- ADPKD is associated with a high incidence of liver cysts that increases with age.
- Signs or symptoms first occur between the ages of 30 and 50 years and include hematuria, flank pain, gastrointestinal symptoms, renal colic, and hypertension.
- Hepatic cysts occur in virtually all patients with ADPKD by the age of 50 years and are rarely symptomatic.
- ICAs of the circle of Willis (berry aneurysm) occur in 10% to 30% of patients, and approximately 9% of these patients die because of subarachnoid hemorrhages.
- The incidence of RCC in ADPKD patients is no higher than that of the general population.
- Tight BP control, the use of ACE inhibitors and/or ARB BP medication, and the possible use of tolvaptan are the most current treatment options.

Juvenile Nephronophthisis and Medullary Cystic Disease Complex

Juvenile NPH (first described by Fanconi et al. in 1951) and medullary cystic kidney disease (MCKD) (first reported by Smith and Graham in 1945) describe a group of genetic (inheritable) disorders with similar and unique characteristics. Similarities include the gross and histopathological appearance of the kidneys, with the hallmark being interstitial fibrosis. Distinguishing features are the mode of inheritance, the age of onset of ESRD, and the type of extrarenal organ involvement. Juvenile NPH is the more common condition and is responsible for 10% to 20% of cases of renal failure occurring in children and occurs in 1% to 5% of patients undergoing dialysis or transplantation (Cantani et al., 1986) (see Table 39.1).

Genetics

Although either condition can occur sporadically, **juvenile NPH usually is inherited as an autosomal recessive trait.** It is genetically heterogeneous, and 13 responsible genes have been identified for various forms of NPH (Hildebrandt et al., 1997; Loftus, 2013; Mollet et al., 2005; Olbrich et al., 2003; Otto et al., 2003, 2005; Saunier et al., 1997; Sayer et al., 2006). The *NPHP1* gene encodes nephrocystin; *NPHP2/INVS*, inversin; *NPHP3*, nephrocystin-3; *NPHP4*, nephrocystin-4/nephroretinin; *NPHP5/IQCB1*, nephrocystin-5; and *NPHP6/CEP290*, nephrocystin-6. *NPHP1* mutations are found in approximately one-half of the patients with NPH. The majority of patients are homozygous for an *NPHP1* deletion (Konrad et al., 1996). *NPHP1, NPHP4, NPHP5*, and *NPHP6* mutations may be associated with the Senior-Loken syndrome (a combination of NPH and retinitis pigmentosa).

MCKD usually is inherited in an autosomal dominant fashion (50% of all offspring will have the disease) and is caused by mutations in either the *MCKD1* or *MCKD2* gene. The *UMOD* gene encodes for uromodulin, the most abundant protein found in normal human urine. Mutations in this gene can also lead to MCKD type 2 (Loftus, 2013). Because patients with either condition theoretically can be fertile in their early childbearing years, the risk of transmitting the condition to offspring must be acknowledged: 1% for juvenile

NPH and 50% for MCKD (Neumann et al., 1997).

Clinical Features

Juvenile NPH and MCKD cause polydipsia and polyuria in more than 80% of patients, but not to the extent observed in patients with diabetes insipidus (Cantani et al., 1986; Gardner and Evan, 1984). The polyuria is caused by a renal tubular urinary concentrating defect that leads to salt wasting, and this process is resistant to vasopressin. Subsequently, a large dietary salt intake frequently is necessary. One major difference in the two entities is the presence of hypertension. There is no hypertension associated with juvenile NPH, whereas patients with MCKD can have significant hypertension.

Renal failure usually ensues 5 to 10 years after initial presentation (Cantani et al., 1986). Another important difference between the two entities is that **renal failure develops in patients with NPH at a mean age of 13 years and almost always before 25 years** (Neumann et al., 1997). MCKD is a milder disease when it manifests in early adulthood, but it will manifest in all patients by 50 years of age (Bernstein and Gardner, 1979). **ESRD in patients with MCKD most often develops in the third or fourth decade.** MCKD type 1 manifests as slowly progressive chronic renal disease. There is minimal proteinuria and hematuria, and hypertension and hyperuricemia become more common as the renal disease progresses. Hyperuricemia is characteristic of MCKD2, and gout is a common presentation in teenage males. Proteinuria is minimal (Bleyer, 2003; Loftus, 2013).

Twenty percent of juvenile NPH families have extrarenal manifestations, whereas MCKD usually affects only the kidneys (Neumann et al., 1997). Sixteen percent of patients with juvenile NPH have associated **retinitis pigmentosa** (Hildebrandt et al., 1993). When the two entities coexist, the condition is referred to as *renal-retinal* or *Senior-Loken syndrome*. More rarely, other conditions can also be present, such as skeletal abnormalities; hepatic fibrosis; Bardet-Biedl syndrome (combination of obesity, mental retardation, polydactyly, retinitis pigmentosa, and hypogenitalism); ocular motor apraxia (Cogan syndrome); and other neurologic defects varying from subtle cerebellar involvement to clear Joubert syndrome (JS) phenotypes, peripheral dysostosis (cone-shaped epiphyses), or truncal cerebellar ataxia (Hildebrandt and Orman, 2001).

Pathologically, NPH and MCKD are similar. Grossly, the kidneys are small to normal in size with multiple cysts at the corticomedullary junction. Histologically, there is a characteristic triad present that includes (1) irregular thickening and disintegration of the tubular basement membrane, (2) marked tubular atrophy with cyst development, and (3) interstitial cell infiltration with fibrosis.

Evaluation

Diagnosis of NPH and MCKD can be difficult early in the onset because of the relative vagueness and nonspecificity of symptoms; thus a high index of suspicion is required. Ultrasonography frequently fails to detect cysts because they are small (Ala-Mello et al., 1998; Chang and Udupa, 1989). Ultrasonography may show smaller-than-normal kidneys in juvenile NPH. Cysts may be seen on imaging studies if they are large enough (Rosenfeld et al., 1977), but, early in the disease, cysts are rarely visible. The parenchyma may also appear hyperechogenic secondary to tubulointerstitial fibrosis (Fig. 39.13; Resnick and Hartman, 1990). Contrast-enhanced CT and MRI scans are more sensitive for detecting small corticomedullary and medullary cysts, but failure to detect cysts does not exclude the diagnosis.

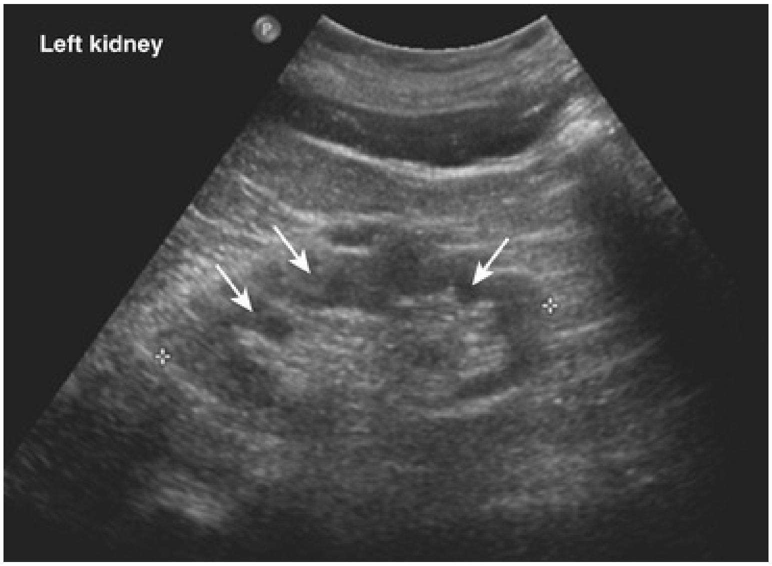

FIG. 39.13 Features of medullary cystic kidney disease. Ultrasonogram demonstrating corticomedullary cysts, some of which are indicated by *arrows.* The hyperechogenicity is secondary to the tubulointerstitial fibrosis. (From Simms RJ, Eley L, Sayer JA: Nephronophthisis. *Eur J Hum Gen* 17:406–416, 2009.)

Treatment

The treatment of NPH is supportive. Because of the tendency for sodium wasting, volume contraction, and renal azotemia, sodium replacement is indicated early in the course of the disease, and unnecessary sodium restriction or use of diuretics should be avoided. Later, dialysis and transplantation must be considered. Allografts apparently are not susceptible to the same process that destroyed the native kidney, because there is no evidence of serum antibodies to the basement membrane or other renal structural proteins (Cantani et al., 1986; Cohen and Hoyer, 1986). If kidneys from siblings are considered for transplant surgery, precautions should be taken to obtain them only from unaffected, older relatives, who should be subjected to meticulous diagnostic evaluation.

Key Points: Juvenile Nephronophthisis and Medullary Cystic Disease Complex

- Juvenile NPH, an autosomal recessive disease, is responsible for 10% to 20% of cases of renal failure in children and leads to early ESRD (early teens).
- MCKD, an autosomal dominant disease, manifests in early adulthood.
- Polyuria, polydipsia, and hypertension are clinical hallmarks of these disease entities.
- Both juvenile NPH and MCKD have almost identical histology, with severe interstitial nephritis; many patients demonstrate cysts at the corticomedullary junction.

Other Inheritable Renal Cystic Diseases (Congenital Nephrosis)

Congenital nephrosis is predominantly of two types. The more common variety is referred to as *congenital nephrotic syndrome of the Finnish type* (CNF) (Lanning et al., 1989; Norio, 1966) and is recessive. The second type is referred to as *diffuse mesangial sclerosis* (DMS), and one-third are familial (Habib and Bois, 1973; Habib et al., 1989). These conditions are associated with dilation of the proximal convoluted tubules, and the patients have profound proteinuria. In infants with CNF, proteinuria is present in the first urinalysis. Without dialysis, half of the patients die by the age of 6 months, and the rest die before their fourth birthday (Huttunen, 1976). In DMS, the onset of symptoms is variable, and the diagnosis is usually made by the age of 1 year. All children have terminal renal failure by the age of 3 years. Approximately one-third of DMS cases are associated with Drash syndrome (nephrotic syndrome and Wilms tumor with or without male pseudohermaphroditism) (Habib et al., 1989). Interstitial fibrosis is present in both conditions but is more pronounced in DMS (Norio and Rapola, 1989). After the kidneys have failed, transplantation is curative. Neither type of disease responds to corticosteroids.

Familial Hypoplastic Glomerulocystic Kidney Disease (Cortical Microcystic Disease)

Cortical microcystic disease is an autosomal dominant disorder described in several families and has been called *hypoplastic glomerulocystic disease* (Rizzoni et al., 1982) and cortical microcystic disease (Kaplan et al., 1989a; Melnick et al., 1984). The diagnosis of familial hypoplastic glomerulocystic disease requires four features: (1) stable or progressive chronic renal failure, (2) small or normal-sized kidneys with irregular calyceal outlines and abnormal papillae, (3) presence of the condition in two generations of a family, and (4) histologic evidence of glomerular cysts.

Multiple Malformation Syndromes With Renal Cysts

Renal cysts are a feature of several syndromes characterized by multiple malformations (see Table 39.1). Tuberous sclerosis and VHL disease are autosomal dominant disorders and are the ones most likely to be encountered by urologists. Meckel syndrome, Jeune asphyxiating thoracic dystrophy, and Zellweger cerebrohepatorenal syndrome are some of the autosomal recessive syndromes. Many of these conditions involve glomerular cysts, and some have cystic dysplasia as a feature.

Tuberous Sclerosis Complex

Bourneville described tuberous sclerosis in 1880. It is usually an autosomal dominant neurocutaneous disorder with an incidence of up to 1 in 6000 individuals (O'Hagan et al., 1996; Webb et al., 1991). It is characterized by benign growths called *hamartomas,* which can develop in nearly every organ of the human body.

Classically, tuberous sclerosis has been described as the triad of Bourneville phakomatosis (epilepsy) (80% of patients), mental retardation (60% of patients), and adenoma sebaceum (facial angiofibromata) (75% of patients) (Lagos and Gomez, 1967; Pampigliana and Moynahan, 1976). It is also associated with autism and other neurocognitive and behavioral disabilities (Kohrman, 2012). Adenoma sebaceum consists of firm, discrete, red or brown telangiectatic papules located in the nasolabial folds, chin, and cheeks. They usually appear after the age of 2 years, gradually become more prominent with time, and persist throughout life. An earlier skin lesion that is a white papule in the shape of an ash leaf is sometimes identified (Shepherd et al., 1991). An examination of the skin with ultraviolet light may reveal cutaneous lesions earlier and should be part of a diagnostic evaluation.

Definitive diagnosis, however, is no longer dependent on this triad but rather on the presence of certain major and minor clinical features (Roach et al., 1998). The diagnosis of tuberous sclerosis complex (TSC) requires two major features (major features include renal angiomyolipoma [AML], facial angiofibromas or forehead plaques, nontraumatic ungual or periungual fibroma, three or more hypomelanotic macules, shagreen patch, multiple retinal nodular hamartomas, cortical tuber, subependymal nodule, subependymal giant cell astrocytoma, cardiac rhabdomyoma, lymphangioleiomyomatosis) or one major plus two minor features (minor features include multiple renal cysts, nonrenal hamartoma, hamartomatous rectal polyps, retinal achromic patch, cerebral white matter radial migration tracts, bone cysts, gingival fibromas, "confetti" skin lesions, multiple enamel pits).

The kidneys of these patients may be free of lesions (Stillwell et al., 1987) or may display cysts, AMLs, or both (Figs. 39.14 and 39.15).

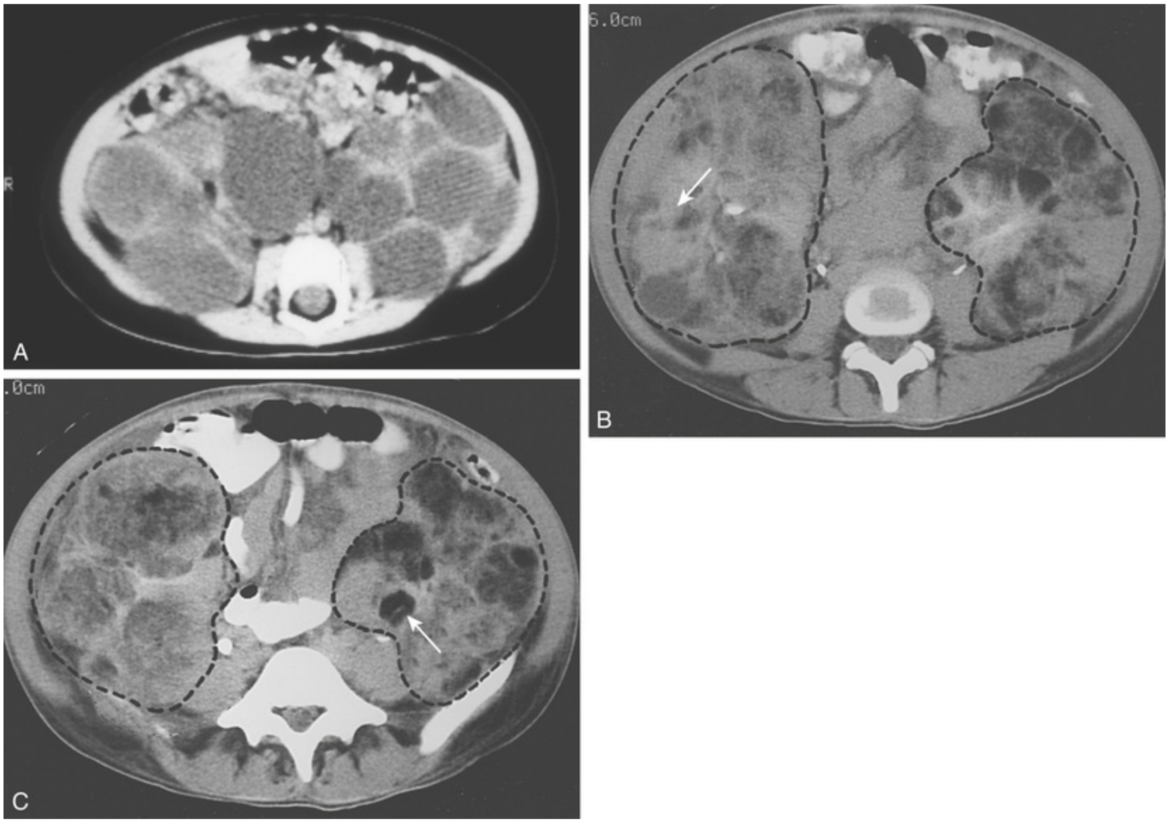

FIG. 39.15 (A) Computed tomography (CT) scan of 4-month-old with tuberous sclerosis complex and diffuse renal cysts. (B and C) A 24-year-old woman was known to have had tuberous sclerosis since early childhood. Enhanced CT scans demonstrate bilateral renomegaly with multiple renal cysts and angiomyolipomas. (B) *Arrow* points to a cyst with a CT value of +10 HU. (C) *Arrow* points to an angiomyolipoma with a negative CT value (−50 HU) secondary to its high fat content. (A, Courtesy Walter Berdon, MD.)

Genetics

Although it is transmitted as an autosomal dominant trait in 25% to 40% of patients, in the remainder, tuberous sclerosis occurs either sporadically or as an example of the genetic condition with variable or incomplete penetrance. Because it is a heterogeneous genetic disorder with variable manifestations, it usually is referred to as TSC. It is caused by mutations in one of two genes. ***TSC1* is located on chromosome 9 (9q34) and encodes the protein hamartin, and *TSC2* is on chromosome 16 (16p13) and encodes the protein tuberin** (Dabora et al., 2001; Jones et al., 1999; Sancak et al., 2005). Both of these genes are characterized as tumor suppressor genes, and the loss of function of either gene leads to hamartoma formation. Hamartin and tuberin function as a complex to inhibit the mTOR pathway. This pathway modulates cell signaling pathways that are important in the regulation of cell growth and migration, as well as cell number and organ size. Therefore a mutation of either gene will lead to similar clinical manifestations (Fig. 39.16).

Clinical Features

Renal involvement in TSC is second only to central nervous system abnormalities and includes predominately AML, renal cysts, and RCCs. AMLs are extremely common in TSC and are usually bilateral and multiple and affect both genders, whereas in the general population they are uncommon, are usually single, and are found mainly in middle-aged women. **Renal AMLs occur in 40% to 80% of patients with TSC** (Chonko et al., 1974; Gomez, 1979). They are rarely identified before the age of 6 years but are common after age 10 years (Bernstein and Gardner, 1986). The primary risk of these lesions relates to their potential for hemorrhage or mass effect. Abdominal or flank mass and tenderness, hypertension, and renal insufficiency can also occur as a result of these lesions. By themselves, these lesions probably do not cause renal failure (Bernstein and Gardner, 1986; Okada et al., 1982). Also, belying their aggressive histologic appearance, which is characterized by pleomorphism and mitoses, no evidence of metastases has been presented.

Unlike AMLs, renal cysts may be present in the first year of life, and cystic disease may be the presenting manifestation of TSC. **Renal cysts develop in approximately 20% of patients and most often manifest before 3 years of age; one-third of children are younger than 1 year of age at presentation.** Patients with large cysts or PKD may be identified by in utero ultrasonography or may demonstrate an abdominal mass and distended abdomen in the first year of life. Most patients with renal cysts do not develop any serious renal compromise, but when the disease is more widespread within the kidney and large cysts are present, renal failure may develop in the milder form with PKD. If any renal failure develops, it is uncommon before the fourth decade (Glazier et al., 1996).

TSC2 and *PKD1* lie adjacent to each other in a tail-to-tail orientation on chromosome 16 at 16p13.3. Deletions inactivating both genes are associated with PCKs diagnosed during the first year of life or early childhood (*TSC2*/*PKD1* contiguous gene syndrome) (Brook-Carter et al., 1994; Sampson et al., 1997). **Therefore TSC should be considered in children with renal cysts and no family history of PKD.** Rarely, *TSC2/PKD1* contiguous gene syndrome can be diagnosed in adults (Martignoni et al., 2002). Patients with the contiguous gene syndrome usually reach ESRD at an earlier age than patients with ADPKD alone. Patients with *TSC1* or *TSC2* mutations without the contiguous gene syndrome also have an increased frequency of renal cysts. The combination of cystic kidneys and AMLs has been said to be virtually pathognomonic for tuberous sclerosis.

Association With Renal Cell Carcinoma

The numerous reports of RCC in patients with tuberous sclerosis make it clear that this association is more than coincidental and may be as frequent as 2% (Bernstein, 1993; Bernstein and Gardner, 1986). However, the incidence of RCC is considerably less than that seen in VHL disease and ARCD of chronic renal failure. Compared with sporadic RCCs, there is a female predominance, earlier age of presentation, and increased bilaterality. Early detection is essential. RCC should be suspected in cases of enlarging lesions without demonstrable fat and in the presence of calcifications within the lesions.

Radiographic Evaluation

Sometimes renal cysts and AMLs can be identified by ultrasonography in tuberous sclerosis, the former lesions being sonolucent and the latter having a fluffy, white appearance. When renal cysts are present without AMLs, the ultrasonographic appearance of the kidneys in tuberous sclerosis is very similar to that in ADPKD. Therefore it is not that unusual for a patient with cysts identified as typical of ADPKD to be diagnosed as having ADPKD, only to develop the stigmata of tuberous sclerosis a few years later. To help make the diagnosis, abdominal CT can be useful in demonstrating AMLs that may be present in the kidney or other organs (findings that are compatible with tuberous sclerosis) and in revealing cysts in other organs (compatible with ADPKD) (see Fig. 39.15). MRI or CT of the head may demonstrate the classic cranial calcifications associated with tubers or gliosis (Okada et al., 1982).

In recent years, it has become increasingly evident that there is a subcategory of AMLs that are “fat poor” and are more difficult to diagnose than the classic AML, which has a characteristic appearance on CT and US. These lesions are benign and do not require extirpative surgery. It is thus important to distinguish these benign lesions from their malignant counterparts. Fat-poor AMLs are subcategorized as follows: (1) hyperattenuating subtype, (2) isoattenuating subtype, and (3) angiomyolipoma with epithelial cyst subtype. The radiologic diagnosis of renal AML is as important as ever. The failure to diagnose the classic and fat-poor types will contribute to unnecessary surgery. Fat-poor AMLs demonstrate specific perfusion features on specialty CT scans allowing their differentiation. It is important to keep this in mind when evaluating unusual renal masses (Chen et al., 2018; Jinzaki et al., 2017; Park, 2017).

Treatment

Because more patients with TCS now survive their central nervous system lesions than in the past, the urologist is more likely to be asked to manage the renal problems (Stillwell et al., 1987). Shepherd et al. (1991) found that renal disease was the leading cause of death in these patients (11 of 40 deaths). Of these 11 patients, 2 died of metastatic RCC, 2 of massive hemorrhage associated with renal AMLs, and 6 of renal failure secondary to the cysts, AMLs, or both.

AMLs are benign lesions that usually are asymptomatic and do not require treatment. Large AMLs are more likely to bleed. van Baal et al. (1994) recommended careful monitoring of the size of AMLs and prophylactic embolization or surgical excision if they enlarge to greater than 4 cm. Annual surveillance with RUS or CT is necessary to assess for growth of the lesions and to detect the development of other complications. Renal-sparing surgery is indicated for symptoms such as pain and hemorrhage, growth of the lesions to the point at which they compromise renal function, and the inability to exclude RCC. Reports of hemorrhagic complications during pregnancy have led to the recommendation that patients with multiple or large AMLs be warned about the potential risk of pregnancy and estrogen administration.

Hypertension and renal failure must also be treated appropriately. Bilateral nephrectomy should be considered before transplantation because of the risk of life-threatening hemorrhage and the development of RCC.

Finally, treatment in rodent models of TSC with rapamycin before the onset of disease reduces the development of renal tumors without affecting the number of precursor lesions (Kenerson et al., 2005). Clinical trials of the mTOR inhibitor rapamycin have demonstrated reduction in the size of tuberous sclerosis–associated renal, lung, and brain tumors. Sirolimus (rapamycin) and everolimus have demonstrated reduction in size of subependymal giant cell astrocytomas, reduction in seizure frequency, and inhibition of AML growth and even reduction of AML size in some reports (Kohrman, 2012). Larger-scale randomized controlled trials of mTOR inhibitors continue.

Elucidation of the TSC protein function at a molecular level and preclinical studies have identified mTOR as a target for intervention in TSC (Budde et al., 2012; Curatolo et al., 2012, Lee et al., 2005). The efficacy of mTOR inhibitors has also been demonstrated in patients with TSC who have subependymal giant cell astrocytomas or pulmonary lymphangioleiomyomatosis (Davies et al., 2011; Franz et al., 2006). Multiple open-label, nonrandomized studies have shown that sirolimus produces a reduction in the volume of renal AMLs, mostly achieved in the first few months of treatment (Bissler et al., 2008; Curatolo et al., 2012; Sasongko et al., 2015), but the effect is not maintained after discontinuation of treatment. The best data on the efficacy of mTOR inhibitors come from the double-blind EXIST-2 study (Everolimus for angiomyolipoma associated with tuberous sclerosis complex or sporadic lymphangioleiomyomatosis) (Bissler et al., 2013), which included 118 patients, 18 years or older, who had a definite diagnosis of TSC ($n = 113$) or sporadic lymphangioleiomyomatosis (LAM) ($n = 5$) and at least one renal AML 3 cm or more in its largest diameter. The patients were randomly assigned in a 2 : 1 ratio to everolimus 10 mg/day or placebo and treated for a median duration of 38 or 34 weeks, respectively. At the data cutoff, therapy had been discontinued in 20 patients, because of disease progression in 9 receiving placebo and because of adverse effects in 1 receiving everolimus and 4 receiving placebo. The primary end point, at least a 50% reduction in the total volume of all target AMLs identified at baseline, was achieved in 42% of the patients treated with everolimus and in none of the patients treated with placebo ($P < 0.001$). The median time to response to everolimus was 2.9 months. Progression of AMLs was significantly more common in the placebo group (21% vs. 4%). The response rate of skin lesions was significantly more common with everolimus (26% vs. 0). The patients treated with everolimus had significantly higher rates of stomatitis (48% vs. 8%) and acnelike skin lesions (22% vs. 5%). On the basis of these findings, the FDA approved everolimus tablets for the treatment of adults with renal AMLs and TSC who do not require immediate surgery. At present, the place of everolimus or other mTOR inhibitors for the treatment of renal AMLs needs to be further defined. Benefits and risks must be balanced, because the administration of mTOR inhibitors can be associated with significant adverse events, the reduction in renal AML volume is reversible after discontinuation of treatment, and long-term outcome results are not available.

von Hippel-Lindau Disease

In 1904 Eugene von Hippel, a German ophthalmologist, first described retinal angiomatosis—angiomatous lesions of the retina that caused blindness in association with similar cerebellar tumors. One of his patients developed renal cancer, and this was reported in 1921. In 1926 Arvid Lindau, a Swedish pathologist, published a series about patients with retinal and cerebellar tumors, with four of his patients also having renal cysts and renal cancer. He was also the first to propose that these lesions had an inherited origin.

VHL disease is an autosomal dominant syndrome manifesting with cerebellar and retinal hemangioblastomas; cysts of the pancreas, kidney, and epididymis; epididymal cystadenoma; pheochromocytoma; and clear cell RCC. It is found in all ethnic groups, both sexes are affected, and it has an incidence ranging from 1 in 30,000 to 1 in 50,000 individuals. It has more than 95% penetrance by the age of 65 years in affected individuals. It is grouped with the phakomatoses (Sturge-Weber-Krabbe syndrome, TSC, and neurofibromatosis), because they all have a common inheritance pattern and propensity for neoplasm.

Etiology

VHL disease is caused by a germline mutation in the tumor suppressor gene known as *VHL*, located on chromosome 3 (3p25) (Kondo and Kaelin, 2001; Latif et al., 1993; Lesho, 1994). A tumor suppressor gene is one in which both copies of the gene must be disabled for a cancer to develop. Seventy percent of patients will have a mutation of one *VHL* allele. As long as one copy of the *VHL* gene is producing functional VHL protein in each cell, tumors do not form. If a mutation occurs in the second copy of the *VHL* gene during a person's lifetime, the cell will have no working copies of the gene and will produce no functional VHL protein. A lack of this protein allows tumors characteristic of VHL syndrome to develop. The discovery and characterization of the *VHL* gene, and its role in cell regulation, is a prime example of how discoveries in the basic science arena can revolutionize treatment of human disease (Clark and Cookson, 2008).

The protein encoded by the *VHL* gene (pVHL) is a tumor suppressor and acts through multiple routes. It forms a complex of proteins that are involved with specific target proteins, typically hypoxia-inducible factors (HIFs), being “marked” for degradation. The most researched of these targets is hypoxia-inducible factor-1α (HIF-1α), a transcription factor that induces the expression of a number of angiogenesis-related factors (Czyzk-Krzeska and Meller, 2004). HIF-1α, when not suppressed, can stimulate the formation of hemangioblastomas and RCC. HIF targets specific genes that encode growth factors that seem to play a role in tumorigenesis, including platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), and vascular endothelial growth factor (VEGF), the last of which is particularly prominent in RCC. HIF-1α and pVHL are also involved in a transcriptional system that is a major regulator in oxygen homeostasis. HIF regulation in normoxia depends on VHL-mediated destruction. When the oxygen supply is reduced, the HIF pathway is activated. Together with activation of HIF in normoxia, VHL-deficient cells show a striking defect in extracellular matrix assembly. Thus altered oxygen tension in pathological settings could have major effects on matrix behavior (Esteban et al., 2004). pVHL has also been shown to be a ciliary protein that controls ciliogenesis in kidney cells. Cilia play an important role in several biologic processes, including mechanosensation, photoperception, and osmosignaling. Loss of pVHL appears to impede the formation of cilia in renal cancer cells, whereas the expression of pVHL in VHL-negative renal cancer cells rescued the ciliogenesis defect (Schermer et al., 2006).

Clinical Features

The mean age at presentation is 35 to 40 years (Neumann et al., 1997). There is no sex preference for the disease or for RCC development. Sporadic RCC in individuals without VHL disease occurs more often in males and usually after age 50 years. **Renal cysts, the most common and often earliest manifestation, are seen in 76% of patients** (Levine et al., 1982). The cysts are bilateral in 75% of affected persons and multifocal in 87% (Reichard et al., 1998). RCC occurs in approximately 50% of affected persons. The renal cysts, as well as the tumors, usually are asymptomatic, although large tumors may cause pain or a mass. Hematuria may occur after rupture of the tumor into the pelvicalyceal system. When cysts are present, typically they are large. Only rarely do images demonstrate ADPKD, and even less often do cysts cause renal failure.

Pheochromocytoma occurs in 10% to 17% of affected persons and appears to be confined to specific families (Horton et al., 1976; Levine et al., 1982). Patients may have seizures or dizziness secondary to hemangioblastomas of the central nervous system. **Cerebellar hemangioblastomas** usually become symptomatic between 15 and 40 years of age (Jennings and Gaines, 1988). These lesions are the most frequent, characteristic, and clinically specific tumors seen in VHL (Shehata et al., 2008; Zbar et al., 1996). Although benign tumors, they often result in major morbidity and mortality. They cause a mass effect because of their location, and, because of their vascular nature, they tend to rupture and bleed. **Retinal angiomas** (hemangiomas) frequently manifest early. Bleeding may cause blurred vision, retinal detachment, and blindness. Early diagnosis is important, because these tumors respond to laser therapy or cryotherapy. The pancreas is commonly involved with either cysts or true neoplasms. **Pancreatic cysts** can occur in up to 70% of patients with VHL but are usually asymptomatic and benign. Islet cell tumors occur in approximately 12% of VHL patients, and metastatic RCC of the pancreas is not unusual (Cheng et al., 1997; Kogire et al., 2000). Other clinical findings in patients with VHL can include **endolymphatic sac tumor, which is a papillary tumor of the petrous bone and can cause hearing loss; papillary cystadenomas of the epididymis; and the female counterpart, cystadenoma of the broad ligament** (Shehata et al., 2008; Zbar et al., 1996).

Because of the high incidence of RCC in patients with VHL disease, the urologist's primary role is careful surveillance so that small tumors can be identified and treated before they metastasize. Although central nervous system hemangioblastomas account for more than half of the deaths in these patients, metastatic RCC is also a major cause of mortality and in some accounts is the leading cause of death in this population (Maher et al., 1990; Reichard et al., 1998). Accordingly, annual or perhaps biannual CT examinations are advised.

Classification

Patients with VHL are subdivided into groups based on disease presentation, and each group has a specific *VHL* gene aberration. VHL type 1 is the most common form of the disease and is characterized by a tendency to develop tumors in the eyes, brain, spinal cord, kidney, and pancreas. VHL type 2 is less common. VHL type 2 differs from type 1 in that affected family members are at high risk to develop pheochromocytomas. VHL type 2 is further divided into types 2A, 2B, and 2C. Individuals in families with VHL type 2A develop pheochromocytomas but have a low risk for RCC (this type of VHL is uncommon). Those with VHL type 2B develop pheochromocytomas and have a high risk for RCC. Patients with type 2C VHL have familial pheochromocytoma without hemangioblastomas and clear cell RCCs (Table 39.3; Shehata et al., 2008; Zbar et al., 1996).

TABLE 39.3

Classification of von Hippel-Lindau Disease

TYPE	CLINICAL CHARACTERISTICS
1	Without pheochromocytoma
2	With pheochromocytoma
2A	Without renal cell carcinoma or pancreatic cysts

2B	With renal cell carcinoma and pancreatic cysts
2C	Familial pheochromocytoma without hemangioblastomas and clear cell renal cell carcinoma

Histopathology

When present, renal cysts and tumors often are multiple and bilateral. The cysts usually simulate simple benign cysts, with flattened epithelium that some investigators consider precancerous. In VHL patients, cysts larger than 2 cm are more likely than smaller cysts to have components of RCC (Poston et al., 1993). Frank cancer usually appears between the ages of 20 and 50 years (Jennings and Gaines, 1988). Others found that the hyperplastic cells lining cysts frequently resembled the clear cell type of RCC, the most common type in these patients (Loughlin and Gittes, 1986). Ibrahim et al. (1989) studied the cysts adjacent to carcinomas and found, much as in tuberous sclerosis, that the karyotype resembled that of the tumors. This similarity is evidence that the hyperplastic cells of the cyst lining are precursors of the carcinomas.

Solomon and Schwartz (1988) believed that a spectrum of pathology is found within the kidneys of patients with VHL disease. At one extreme is a simple cyst with a single layer of bland epithelium. The next step is a typical proliferative cyst with layers of epithelial cells. In the ensuing step, there are complex neoplastic projections into the cyst lumen. If the arbitrary distinction between adenoma and carcinoma on the basis of size is agreed upon, the next stage would be adenoma. Finally, there is full-blown RCC. All of these stages may be found within a single kidney (Solomon and Schwartz, 1988).

Evaluation

In patients with a known family history of VHL, the diagnosis can be made based on the presence of a single retinal or cerebellar hemangioblastoma, RCC, or pheochromocytoma (Couch et al., 2000; Melmon and Rosen, 1964). In such families, germline mutations may be present without clinical manifestations, and the patient should be screened for this mutation. For patients who do not have a family history, the diagnosis requires two or more cardinal manifestations, such as retinal or cerebellar hemangioblastomas, or a single hemangioblastoma and an additional characteristic lesion.

Ultrasonography is useful in diagnosing the typical benign renal cystic features of VHL disease: absence of internal echoes, well-defined margins, and acoustic enhancement. On CT, sharp thin walls are seen around homogeneous contents without enhancement after contrast medium injection. Because multiple lesions (cysts, tumors, or both) are often present, CT frequently is more useful than ultrasonography. CT often is useful in examining the adrenal glands for pheochromocytomas.

When the lesions are small, it is impossible to distinguish tumors from cysts. In such cases, patients should have regular CT scans with narrow-screen collimation (Levine et al., 1982). With larger lesions, and whenever RCC is suspected, renal angiography with magnification or subtraction is advisable. This type of study helps to reveal any additional tumors and indicates the appropriateness of conservative surgery (Kadir et al., 1981; Loughlin and Gittes, 1986). Intra-arterial administration of epinephrine is sometimes helpful, because it causes vasoconstriction of the normal vessels but has no effect on tumor neovascularity.

MRI has not been very useful for small tumors of the kidney, unless the shape of the kidney is altered. The lesions on MRI have a signal intensity that is similar to that of normal renal parenchyma on T1- and T2-weighted images. However, gadolinium is useful because it enhances RCC. The heterogeneous nature of the larger tumors makes them more readily diagnosed (Rominger et al., 1992).

Screening

The genetic nature of VHL disease mandates careful screening. However, because of molecular genetic advances, the screening process for the disease in family members can now be more selective. Previously, asymptomatic relatives required routine ophthalmoscopic examination to rule out retinal angiomas, as well as frequent abdominal CT scans. Now only genetically affected family members require screening (Table 39.4).

TABLE 39.4

Screening Protocol for Patients and Families With von Hippel-Lindau Disease

STUDY	AFFECTED PERSONS	RELATIVES AT RISK
Physical examination	Annual	Annual
24-Hour urine collection for metanephrines and	Annual	Annual

normetanephrines		
Funduscopy	Annual	Annual (age 10–60 yr)
Gadolinium MRI brain scan (or CT)	Every 3 yr from age 10-50 yr; every 5 yr thereafter	Every 3 yr from age 15–40 yr then every 5 yr until age 60 yr
Abdominal evaluation	Annual RUS with abdominal CT scan every 3 yr (more frequently if multiple renal cysts present)	Annual RUS with abdominal CT scan every 3 yr from age 20–65

CT, Computed tomography; *MRI,* magnetic resonance image; *RUS,* renal ultrasonography.

Treatment

The treatment of patients with VHL requires a multidisciplinary approach, because the involvement of multiple organ systems and numerous medical problems is inherent to this disease. Because the tumors that characterize VHL disease are frequently multiple, bilateral, and recurrent, the goals of treatment for patients who have VHL disease are not as straightforward as the goals of treatment for patients who have sporadic tumors. Close surveillance and minimization of surgical procedures constitute the mainstay of treatment. **For patients who have VHL disease, and all patients who have hereditary cancer syndromes, the goal of treatment is cancer control, not cancer cure, and preservation of functional parenchyma to avoid the morbidity associated with renal or adrenal loss.** In patients who have VHL disease, surgical resection is performed with the understanding that microscopic disease probably is left behind. At present, open nephron-sparing surgery should be considered the standard of care for treating low-grade RCC in the setting of VHL disease. Patients with high-grade disease are still probably best served with bilateral nephrectomy. With the objective of sparing as much renal parenchyma as possible and preventing metastasis of the lesions already present, it is not curative surgery (Reed and Parekh, 2009). Although this approach does not reduce the risk of recurrence, reported to be 75% to 85%, the 10-year disease-specific survival rates are high (81% to 94%) (Malek et al., 1987; Ploussard et al., 2007; Roupret et al., 2003; Steinbach et al., 1995). Classically, the survival rate after nephrectomy has been only 50%. Because most of these tumors are low grade, a nephron-sparing approach provides very good survival rates while avoiding the diminished quality of life that comes with bilateral nephrectomy and subsequent dialysis and transplantation. Laparoscopic and percutaneous image-guided ablative techniques, such as radiofrequency ablation and cryoablation, have also been used and are currently under investigation.

Given the high risk of multiple and bilateral pheochromocytomas in patients who have VHL disease, bilateral adrenalectomy can lead to the loss of all adrenal function. Preservation of normal adrenocortical function should be a primary surgical goal, because medical replacement therapy is associated with decreased quality of life (Telenius-Berg et al., 1989). Partial adrenalectomy can preserve normal adrenal function and avoid this morbidity. Identification of small pheochromocytomas may enable laparoscopic preservation of adrenal function and maintain quality of life in these complicated patients. The small size and lack of function of these tumors make them ideal for partial adrenalectomy; however, recurrences may develop in 15% of patients (Walther et al., 1999a, 1999b).

Papillary cystadenomas of the epididymis can be unilateral or bilateral and occur in approximately 10% to 26% of men who have VHL disease (Horton et al., 1976; Lamiell et al., 1989). They seem to have no malignant potential. Surgery is not performed for these lesions unless the patient experiences severe pain.

Key Points: Multiple Malformation Syndromes

- Tuberous sclerosis complex is an autosomal dominant condition that includes the triad of epilepsy, mental retardation, and adenoma sebaceum. It is associated with renal cysts (20% of patients), renal AML (40% to 80%), and RCC (2%).
- There are two different gene mutations associated with tuberous sclerosis: *TSC1* on chromosome 9 and *TSC2* on chromosome 16.
- VHL disease is an autosomal dominant syndrome associated with cerebellar and retinal hemangioblastomas; cysts of the pancreas, kidney (76%), and epididymis; pheochromocytoma (10% to 12%); and clear cell RCC (50% incidence, and 30% to 40% incidence of death).
- VHL disease is associated with an inherited mutation of the *VHL* gene on chromosome 3.

- *VHL* is a tumor suppressor gene involved in regulation of HIF target genes, including *VEGF*; abnormal or absent *VHL* leads to increased tissue levels of specific growth factors and, in particular, VEGF, the most prominent growth factor in RCC.

Multicystic Dysplastic Kidney

MCDK is a developmental anomaly resulting in multiple cysts of varying sizes, without identifiable normal renal parenchyma. These kidneys have no function by definition, and usually the contralateral kidney is normal and exhibits compensatory hypertrophy. Only unilateral involvement is compatible with life. The kidney often does not have a reniform appearance, and it is typically associated with an atretic ureter with no connection between glomerulus and calyces. Typically, the kidney has the appearance of a bunch of grapes, with little stroma between the cysts (Fig. 39.17). Renal size is highly variable, ranging from a small nubbin of tissue to a very large mass that fills most of the abdomen. In fact, MCDK is the second most common cause of an abdominal mass in a newborn, after hydronephrosis.

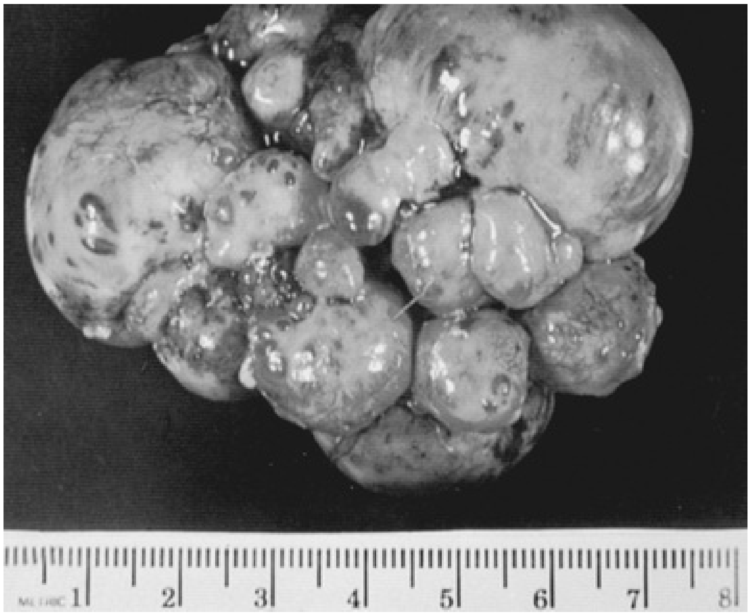

FIG. 39.17 A typical multicystic dysplastic kidney having the appearance of a bunch of grapes. The kidney is composed almost entirely of cysts with very little stroma.

MCDK can be of two types: the infundibulopelvic type, with the atresia involving the renal pelvis and the ureter, and the less common hydronephrotic type, in which only the upper ureter is atretic (Felson and Cussen, 1975). In both cases, the ureters are absent or atretic and the renal vessels are hypoplastic.

MCDK can also rarely be secondary to ureteroceles that have caused complete obstruction. It can rarely be seen in one-half of a duplex kidney (usually the upper pole associated with an ectopic ureter) or in other abnormalities such as a horseshoe kidney.

Etiology

Many theories have been offered to explain the cause of MCDK. Clearly, it is a result of an error in renal development. Some have proposed that the multicystic kidney is an extreme form of obstructive hydronephrosis that occurs secondary to atresia of the ureter or renal pelvis. Several investigators have attempted to establish an animal model of MCDK by ligating the ureter at various points in gestation (Beck, 1971; Fetterman et al., 1974; Tanagho, 1972). This approach is not effective in middle or late gestation; early ligation of the fetal lamb ureter produces renal dysplasia but not multicystic dysplasia (Beck, 1971). Similarly, other investigators have been able to induce dysplasia, but no one as yet has been able to induce an MCDK.

Another theory stems from the “ureteric bud theory” as proposed by Mackie and Stephens (1975). This theory hypothesizes that MCDK may result from abnormal interaction between the ureteric bud and metanephric mesenchyme. Mutations in genes such as *EYA1*, *SIX1*, *WNT*, *WT-1*, *GNF*, *AT2*, and *PAX2* are known to have important roles in ureteric bud development and have been identified in multiple human syndromes with renal dysplasia (Pope et al., 1999). These studies linking genetic mutations with renal dysplasia support the ureteric bud theory in the pathogenesis of MCDK and may also explain its frequent association with other urinary tract anomalies (Hains et al., 2009). This hypothesis, like the obstructive view, is supported by the high incidence of concomitant ureteral atresia.

Although the ureteric bud theory and the obstruction theory may at some level go hand in hand, there is no question that there are several gene-mediated processes that go awry in the process of making a developmentally abnormal MCDK. These genes and their proteins are currently potential targets for therapeutic intervention and research to further elucidate the mechanisms that cause MCDK.

Clinical Features

Multicystic dysplasia is the most common type of renal cystic disease and is the second most common cause of an abdominal mass in infants (Griscom et al., 1975; Longino and Martin, 1958; Melicow and Uson, 1959). Most cases in the current era are diagnosed by prenatal ultrasonography, and the incidence is 1 per 1000 to 4000 live births (Kalyoussef et al., 2006). There is a male preponderance (55% to 70%), and studies conflict as to whether MCDK is more common on the right or left side.

The contralateral system frequently is abnormal. For example, contralateral UPJO is found in 3% to 12% of infants with MCDK, and contralateral vesicoureteral reflux is seen in 18% to 43% of infants (Al-Khaldi et al., 1994; Atiyeh et al., 1992; Flack and Bellinger, 1993; Heikkinen et al., 1980; Wacksman and Phipps, 1993).

The natural history of MCDK is benign; the incidence of complications is extremely rare; and approximately 40% of MCDKs will spontaneously involute. Although anecdotal case reports exist, available large series data indicate that MCDK is not associated with an increased risk for hypertension or neoplasm (Farnham et al., 2005; Narchi, 2005a, 2005b; Onal and Kogan, 2006; Rabelo et al., 2004; Tilemis et al., 2003; Truong et al., 2003; Wacksman and Phipps, 1993). Although hypertension is a rare but recognized sequela of MCDK, it is reasonable to follow patients with MCDK conservatively. The primary care provider should monitor patients with MCDK for hypertension, abdominal mass, and urinary tract infection.

Histopathology

Multicystic kidneys with large cysts tend to be large with little stroma, whereas those with small cysts typically are smaller and more solid. Likewise, the blood supply is variable, ranging from a pedicle with small vessels to no pedicle at all (Parkkulainen et al., 1959). Usually the ureter is partly or totally atretic, and the renal pelvis may be absent. Griscom et al. (1975) referred to the form without a renal pelvis as *pyeloinfundibular atresia* and reported finding no evidence of communication between the cysts. However, others have shown distribution of contrast medium among the cysts by means of connecting tubules (Saxton et al., 1981). Microscopically, the cysts are lined by low cuboidal epithelium, are surrounded by collars of spindle cells, and are filled with proteinaceous or sanguineous fluid. They are separated by thin septa of fibrous tissue and primitive dysplastic elements, especially primitive ducts. Immature-appearing cartilage is often present in the tissue. Frequently, immature glomeruli are present, and on occasion a few mature glomeruli are seen (Fig. 39.18).

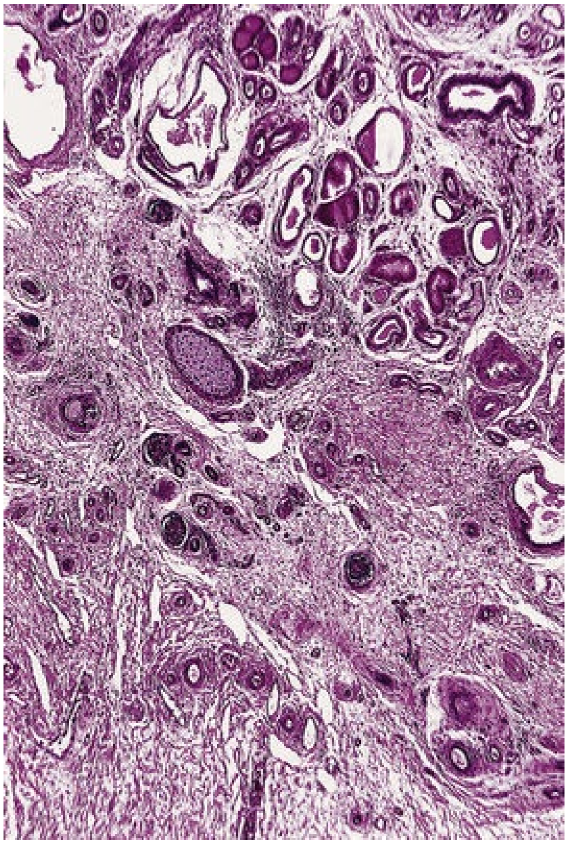

FIG. 39.18 Disorganized development of kidney consistent with multicystic dysplastic kidney showing primitive glomeruli, tubules, and mesenchyme. (From Ordonez NG, Rosai J: Urinary tract. In Rosai J, editor: *Rosai and Ackerman's surgical pathology,* ed 9, Edinburgh, 2004, Mosby.)

Evaluation

MDCK is most often identified by prenatal ultrasonography, and in newborns ultrasonography is usually repeated (once within the first few days of life and again 1 month later) to confirm the diagnosis and to evaluate the contralateral kidney and bladder. In a few cases, it is difficult to differentiate multicystic kidney disease from severe hydronephrosis (Gates, 1980; Hadlock et al., 1981). **In general, the multicystic kidney has a haphazard distribution of cysts of various sizes without a larger central or medial cyst and without visible communications among the cysts. Frequently, very small cysts appear**

among the large cysts. By comparison, in UPJO, the cysts or calyces are organized around the periphery of the kidney, connections usually can be demonstrated between the peripheral cysts and a central or medial cyst that represents the renal pelvis, and there is an absence of small cysts among the larger cysts (Fig. 39.19).

B

FIG. 39.19 (A and B) Renal ultrasonogram of large left multicystic dysplastic kidney. There are multiple large cysts. No definite renal cortex is seen.

In these difficult cases, radioisotope studies may be helpful. **Hydronephrotic kidneys usually show some function on a dimercaptosuccinic acid (DMSA) or technetium-99m mercaptoacetyltriglycine (^{99m}Tc-MAG3) scan, whereas renal uptake is seldom seen in multicystic kidneys** (Fig. 39.20). Angiography reveals an absent or small renal artery in the multicystic kidney, but this study is rarely indicated. Cystoscopy may reveal a hemitrigone and absent ureteric orifice on the affected MCDK side; however, more often an orifice is present, but retrograde urography demonstrates ureteral atresia. Again, this study is seldom performed. As mentioned previously, a voiding cystourethrogram (VCUG) is usually indicated in the workup because of the high incidence of reflux into the contralateral single functioning kidney. Some authors, however, have started to advocate that the VCUG is of little value if serial high-quality ultrasound findings are consistent with MCDK and demonstrate a normal bladder and contralateral kidney. A VCUG is not necessary unless clinically indicated later in life (Ismaili et al., 2005; Onal and Kogan, 2006; Welch and Wacksman, 2005).

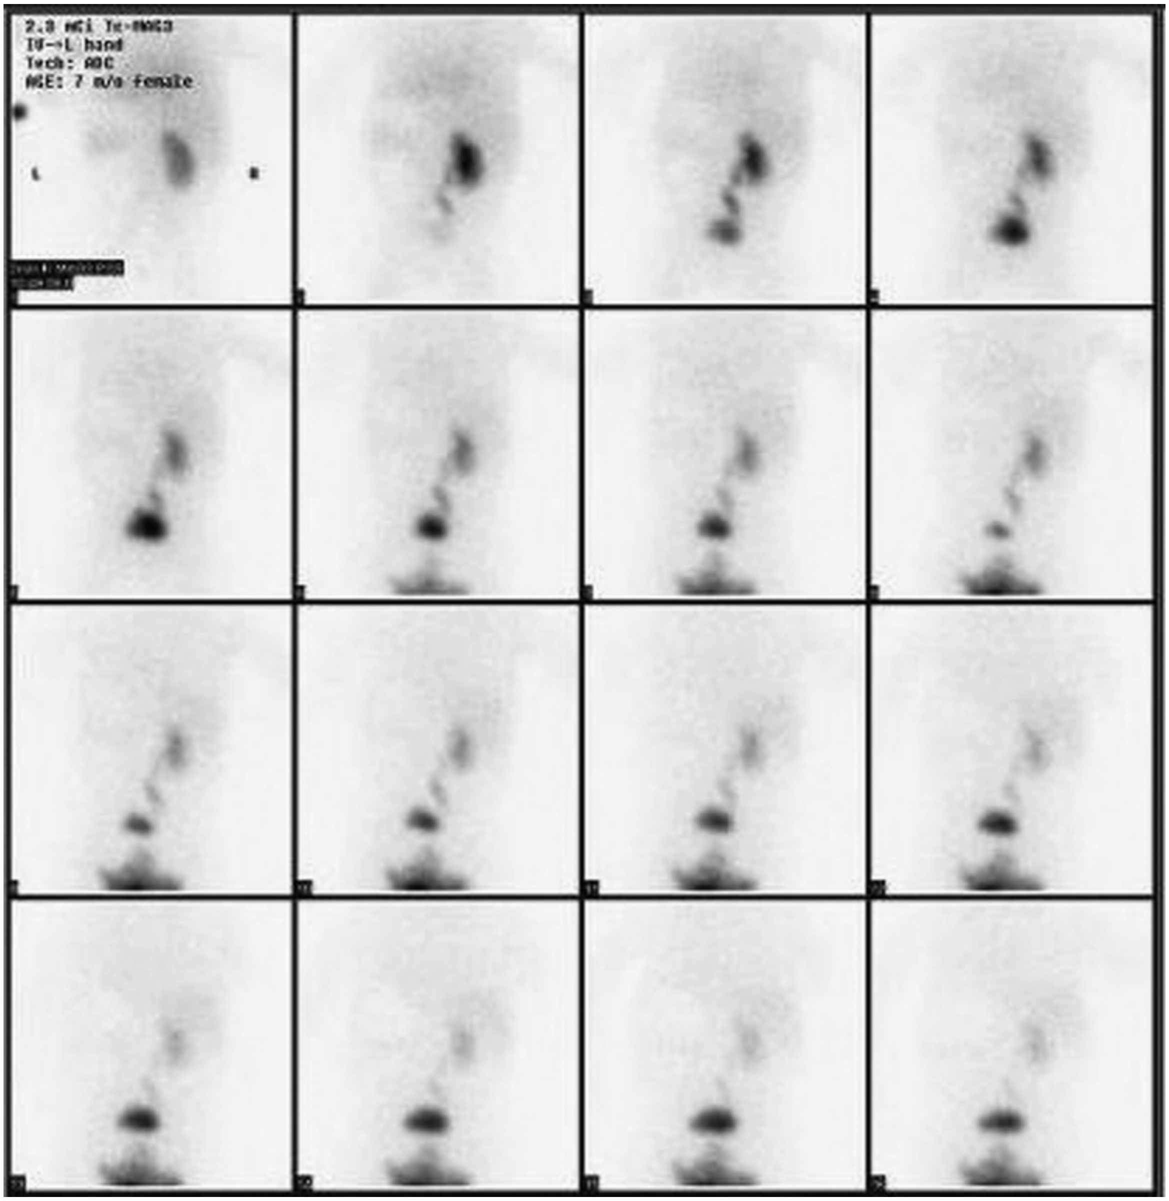

FIG. 39.20 Technetium-99m mercaptoacetyltriglyceride renogram revealing a normally functioning right kidney and no function on the left, which is consistent with a left multicystic dysplastic kidney.

Treatment and Prognosis

It has often been stated that the multicystic kidney can be ignored unless its bulk is inconvenient (Griscom et al., 1975; Pathak and Williams, 1964), and attention should be directed instead to identifying any abnormalities of the contralateral urinary tract. Large MCDKs are known to interfere with respiratory and digestive function simply because of their mass effect. Intervention for these large masses may have to be undertaken to relieve these problems. Nephrectomy for MCDK may also be necessary to correct the rare cases of associated hypertension or if a cyst has ruptured spontaneously or secondary to trauma (to relieve pain or hemorrhage).

A nonfunctioning hydronephrotic kidney could be mistaken for a multicystic kidney, although complete nonfunction on a nuclear medicine study is unusual in kidneys affected by UPJO. Fortunately, if the correct diagnosis is missed in such a case, there are unlikely to be significant consequences, because a totally nonfunctioning hydronephrotic kidney is rarely salvageable and probably will cause no problems other than a predisposition to infection or hypertension.

The probability of malignant transformation is estimated to be extremely low and believed by many to be nonexistent (Avni et al., 1987; Gordon et al., 1988; Narchi, 2005b; Wacksman and Phipps, 1993). Fewer than 15 cases of malignant degeneration have been reported in MCDK. Roughly half have been identified as RCC and half as Wilms tumor, and there has been one reported mesothelioma. Recommendations for addressing this risk range from early nephrectomy of the MCDK to minimal follow-up with no imaging and only periodic abdominal examination by the primary care physician (PCP). Many pediatric urologists will perform ultrasound surveillance every 3 to 12 months, but there has been no conclusive evidence that this is beneficial or cost effective (Onal and Kogan, 2006; Perez et al., 1998).

There has also been much debate in contemporary series regarding hypertension in MCDK. The various case reports and small series that have been reviewed offer conflicting data on the issue. An additional confounding factor is that MCDK is often associated with contralateral abnormalities, such as UPJO and reflux. Thus groups have had difficulty determining if hypertension is associated with contralateral abnormalities or with MCDK. Several small series have reported patients with MCDK and hypertension who were cured with nephrectomy (Angermeier et al., 1992; Javadpour et al., 1970; Snodgrass, 2000; Susskind et al., 1989; Webb et al., 1997). Although these reports demonstrate that hypertension can occur with MCDK, most large series support the rarity of hypertension in association with MCDK. Several studies, including the report from the Multicystic Kidney Registry in 1993, have demonstrated the incidence of hypertension in patients with MCDK and long-term follow-up to be less than 1% (Gough et al., 1995; Farnham et al., 2005; Perez et al., 1998; Wacksman and Phipps, 1993). One study, however, demonstrated a much higher incidence of hypertension than the other MCDK series (Seeman et al., 2001). This could be a result of the more stringent measurement of BP applied, although these patients were examined at a much later age than in other series, which may also have contributed to the higher detected incidence of hypertension. Two of those four patients with hypertension had concomitant abnormalities; thus it was concluded that increased BP is mainly associated with contralateral kidney damage regardless of the presence or absence of the dysplastic kidney (Seeman et al., 2001). In summary, hypertension is a rare but recognized sequela of MCDK. However, there is a suggestion that with more diligent monitoring, its incidence would increase. Therefore it is reasonable to follow patients with MCDK conservatively, realizing that hypertension can exist and should be assessed periodically. Because hypertension can be discovered on an examination by the PCP, the potential for this problem does not require urologic follow-up, only an informed PCP and family (Farnham et al., 2005).

Key Points: Multicystic Dysplastic Kidney

- MCDK is a developmental anomaly resulting in multiple cysts of varying sizes, is without identifiable normal renal parenchyma, is associated with active expression of genes involved with nephrogenesis, and has a changing morphology.
- Kidneys usually get smaller or disappear from view on imaging studies (i.e., renal aplasia), very occasionally increase in size, and very rarely are associated with Wilms tumor.
- There is no clear indication for removal of the kidney, unless an increased amount of solid tissue is identified.
- Large series data indicate that MCDK is not associated with an increased risk for hypertension or neoplasm.
- Fifteen percent of patients have associated contralateral reflux, and debate exists regarding whether or not to obtain a VCUG in all patients or only in those with some degree of fullness in the contralateral collecting system.

Benign Multilocular Cyst (Cystic Nephroma)

Benign multilocular cyst (multilocular cystic nephroma) is a multilocular cystic neoplastic lesion in the kidney that falls in a spectrum of diseases along with multilocular cyst with partially differentiated Wilms tumor, a multilocular cyst with nodules of Wilms tumor, or cystic Wilms tumor (Fig. 39.21). These four lesions form a spectrum, with benign multilocular cyst at the most benign extreme and cystic Wilms tumor at the most malignant extreme. There has been some debate as to whether these lesions represent a spectrum of one disease with a common cause.

Multilocular cystic renal cell carcinoma
Multilocular cyst with nodules of renal cell carcinoma?
Cystic renal cell carcinoma

FIG. 39.21 The spectrum of multilocular cystic lesions in children and adults. There is no evidence that one lesion can convert into the other. Benign cystic partially differentiated Wilms tumor and multilocular cystic renal cell carcinoma act as benign lesions. When nodules of tumor are present, the lesion should be considered malignant, although the prognosis of this lesion, as well as cystic Wilms tumor and cystic renal cell carcinoma, seems to be better than that of the corresponding solid lesions. It is not clear whether clinical examples of "multilocular cyst with nodules of renal cell carcinoma" actually exist, but this entity is placed in the spectrum for consideration. For simplicity, the multilocular-appearing lesions of other cystic tumors (e.g., cystic oncocytoma, cystic hamartoma of the renal pelvis) are not included in the figure.

A multilocular cyst is not a renal segment affected by multicystic kidney disease; these conditions differ clinically, histologically, and radiographically. However, controversy continues about whether the multilocular cyst is a segmental form of renal dysplasia (Johnson et al., 1973; Osathanondh and Potter, 1964; Powell et al., 1951), a hamartomatous malformation (Arey, 1959), or a neoplastic disease (Boggs and Kimmelsteil, 1956; Christ, 1968; Fowler, 1971; Gallo and Penchansky, 1977). The confusion arises in part from the variability of the histologic picture: the appearance of the primitive stroma; the maturity of tubular and even on occasion of muscle elements; and the degree of epithelial atypia that differs not only from patient to patient but also within the same lesion.

Clinical Features

The great majority of cases (95%) manifest before the age of 4 years or after 30 years. If younger than 4 years, the patient is twice as likely to be male; if older than 30 years, the patient is eight times as likely to be female (Eble and Bonsib, 1998).

The signs and symptoms differ according to the age at presentation. **In children, an asymptomatic flank mass is the most common finding, whereas most adults have a flank mass, abdominal pain, or hematuria.** The bleeding is felt to be secondary to herniation of the cyst through the transitional epithelium into the renal pelvis (Aterman et al., 1973; Madewell et al., 1983; Uson and Melicow, 1963).

Seven cases of bilateral benign multilocular cysts of the kidney have been described (Castillo et al., 1991), and recurrence after excision has been rarely described (Geller et al., 1979). There are also at least two instances in which multilocular cysts arose in kidneys known to have been normal previously (Chatten and Bishop, 1977; Uson and Melicow, 1963). Such cases support a neoplastic theory of the origin of this lesion.

Histopathology

These lesions are bulky and are circumscribed by a thick capsule. Normal renal parenchyma adjacent to the lesion frequently is compressed by it. The lesion may extend beyond the renal capsule into the perinephric space or renal pelvis. The loculi, which range from a few millimeters to centimeters in diameter, do not communicate. They contain clear, straw-colored or yellow fluid and are lined by cuboidal or low columnar epithelial cells. In some cases, eosinophilic cuboidal cells project into the cyst lumen, creating a hobnail appearance (Madewell et al., 1983). The septa of a benign multilocular cyst are composed of fibrous tissue in which well-differentiated tubules may be present, but poorly differentiated tissues and blastemal cells are not present (Joshi and Beckwith, 1989).

In children, although there may be a continuum from benign multilocular cyst to cystic Wilms tumor, and although all of these lesions may be derived from similar cells or tissues, no evidence suggests that one entity transforms into another. Furthermore, **none of the genetically determined conditions associated with Wilms tumor (e.g., hemihypertrophy, aniridia) has accompanied a benign multilocular cyst** (Banner et al., 1981).

In adults, there also is a spectrum of multilocular cystic lesions. Multilocular cystic RCC in adults falls in the spectrum between a benign multilocular cyst and a cystic malignant tumor, such as a **multilocular cystic RCC, a cystic RCC, a cystic oncocytoma, or a cystic hamartoma of the renal pelvis** (Eble and Bonsib, 1998; Kirsh et al., 1999). The cystic component of the tumor at the carcinomatosis end of the spectrum in children and adults (i.e., cystic Wilms tumor and cystic RCC) improves the prognosis of the malignant lesion (Kirsh et al., 1999). In adults, as in children, there is no evidence that one lesion can convert into another (Fig. 39.22).

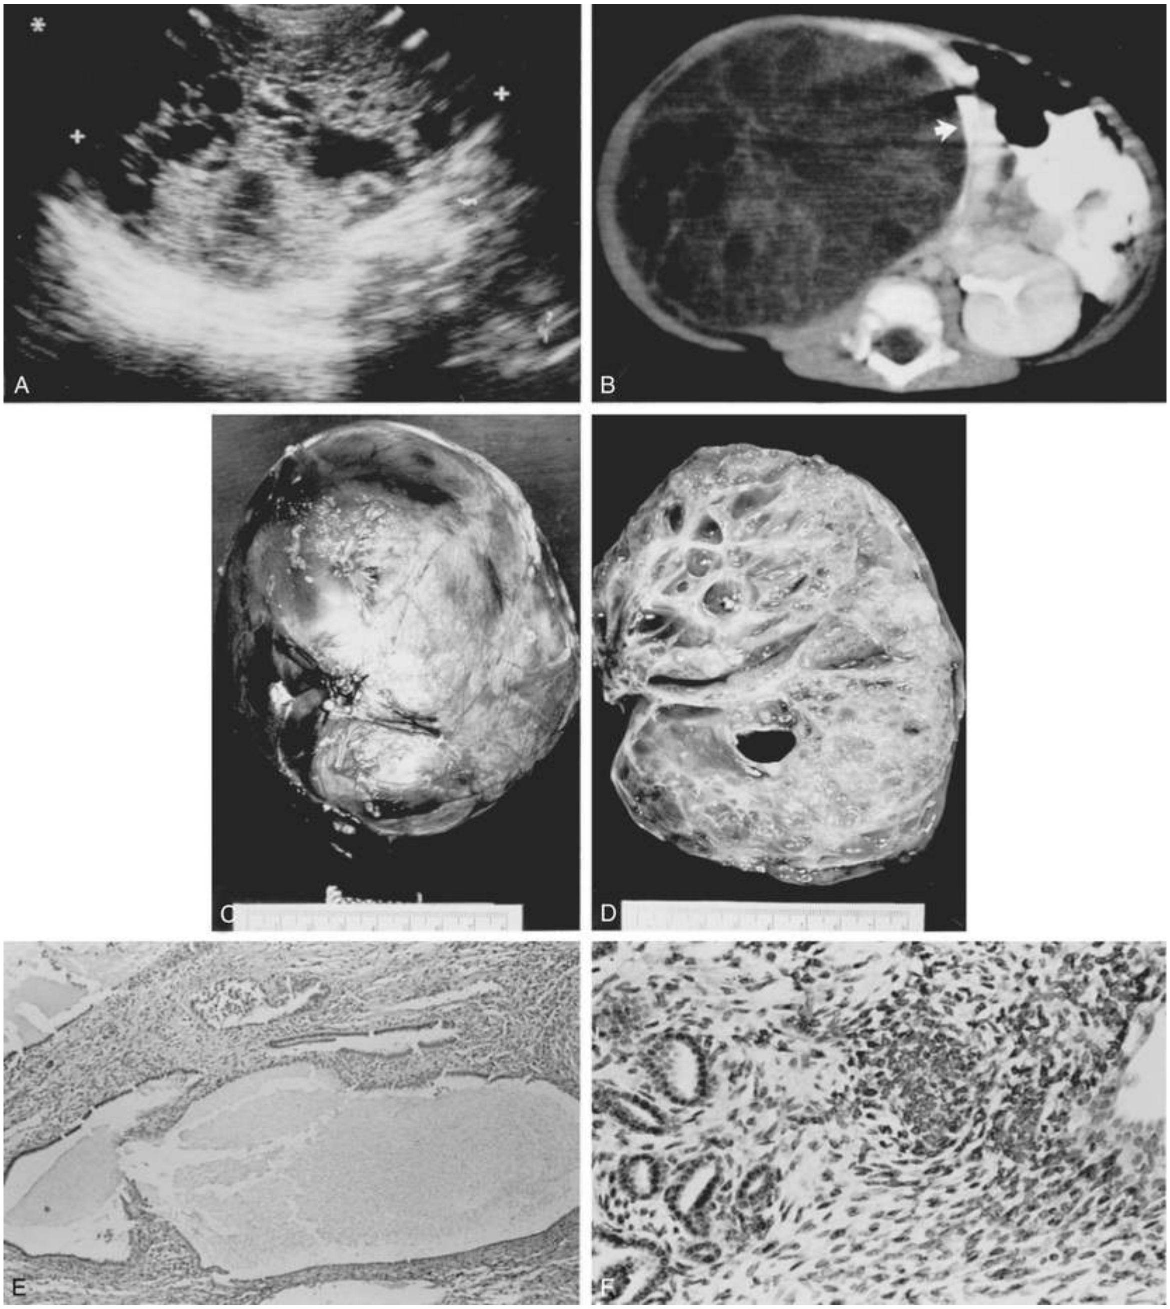

FIG. 39.22 A 4-year-old girl with a right-sided abdominal mass. (A) Renal ultrasonogram shows multiple cysts throughout the left kidney. (B) On contrast medium–enhanced computed tomography scan, a large, smoothly outlined left renal mass is seen with fine septa throughout the mass. Residual preserved parenchyma and the pelvicalyceal system are compressed medially and pushed to the contralateral side *(arrow).* (C) Uncut gross specimen reveals a smooth-walled, encapsulated renal mass. (D) Cross section of mass reveals multiple noncommunicating loculations. (E) On histology, a hypocellular cystic area is seen with monotonous stroma (100×). (F) Between loculi, nests of blastemal cells are visualized

along with tubular elements *(left),* making the diagnosis of multilocular cyst with partially differentiated Wilms tumor (200×).

Evaluation

A number of tests may be useful, including ultrasonography, CT, MRI, cyst puncture with aspiration and double-contrast cystography, and arteriography. **Ultrasonography and CT can distinguish multicystic kidneys from multilocular cysts, but neither study is sufficiently reliable to distinguish among multilocular cysts, multilocular cysts with foci of Wilms tumor or adenocarcinoma, mesoblastic nephromas, cystic Wilms tumors, and clear cell sarcomas.** Typically, the septa are highly echogenic with sonolucent loculi, although if there is debris in a loculus, it may appear more solid. On CT the septa are less dense than normal parenchyma. Calcification is rarely visible in such lesions in children (Madewell et al., 1983).

Treatment

The treatment for any multilocular cystic lesion, even the most benign variant, is nephrectomy. If the lesion is localized enough and there is well-preserved normal tissue, excision of the lesion or partial nephrectomy is feasible. Children who have a multilocular cyst with nodules of Wilms tumor or a cystic Wilms tumor should be treated as for Wilms tumor, according to the National Wilms Tumor Study (NWTS) recommendations for the appropriate stage of disease, recognizing the generally favorable outlook. Similarly, cystic RCC in adults should be managed as a malignant lesion, again recognizing its better prognosis. In adults, benign multilocular cysts more often are associated with larger amounts of normal renal tissue, making partial nephrectomy more often feasible.

If enucleation or partial nephrectomy is chosen, recurrence is possible. However, with more Wilms tumors being treated by local excision, the case for enucleation or partial nephrectomy combined with close follow-up by ultrasonography and CT is stronger, even if malignancy is found within the lesion. By comparison, if a clear cell sarcoma is found after enucleation, the remaining ipsilateral renal tissue should be removed because of the aggressiveness of this cancer. The recurrence of a multilocular cyst not containing malignancy probably reflects inadequate excision of the initial lesion.

Key Points: Benign Multilocular Cyst

- A benign multilocular cyst is a benign, nondysplastic, neoplastic lesion that occurs most commonly either before the age of 4 years, most frequently in males, or after the age of 30 years, predominantly in females.
- The only way to determine the diagnosis of a multilocular cystic lesion identified on imaging studies, in either a child or an adult, is by surgical excision.
- Benign multilocular cyst is thought to fall at the benign end of a spectrum of the same disease process that also includes multilocular cyst with partially differentiated Wilms tumor, multilocular cyst with nodules of Wilms tumor, or cystic Wilms tumor at the most malignant end of the spectrum.

Simple Cysts

Simple cysts are the most common cystic lesions found in the human kidney. They are usually oval to round; may be solitary or multiple, unilateral or bilateral; and are filled with plasmalike clear or straw-colored fluid (Nahm and Ritz, 2000; Terada et al., 2002). They are not connected to any part of the nephron, although they may originate initially from a portion of the nephron.

Simple cysts may manifest at any time in utero and have been diagnosed as early as 14 weeks of gestation. Ultrasonography done on 29,984 fetuses in succession revealed 0.09% of 11,000 pregnancies to have renal cysts (Blazer et al., 1999). Between birth and 18 years of age, the incidence of simple renal cysts is fairly stable, ranging from 0.1% to 0.45%, with an average incidence of 0.22% (McHugh et al., 1991). However, in adults the frequency rises with age, with an incidence of 20% by age 40 years and as high as 50% after age 60 years (Kissane and Smith, 1975; Laucks and McLachlan, 1981).

Clinical Features

In children and adults, cysts are typically discovered incidentally on ultrasonography, CT, or urography. However, cysts can produce an abdominal mass or pain, hematuria secondary to rupture into the pelvicalyceal system, and hypertension secondary to segmental ischemia (Lüscher et al., 1986; Papanicolaou et al., 1986; Rockson et al., 1974). Cysts can cause calyceal or renal pelvic obstruction as well (Barloon and Vince, 1987; Evans and Coughlin, 1970; Hinman, 1978; Wahlqvist and Grumstedt, 1966). They may or may not increase in size with time.

Cysts can rupture into the pelvicalyceal system, maintain a communication, and become a pseudocalyceal diverticulum. The reverse is also possible: closure of the communication of a diverticulum can create a simple cyst (Mosli et al., 1986; Papanicolaou et al., 1986). These two sequences of events can be distinguished only by histologic examination. Theoretically, diverticula should have linings of transitional epithelium, whereas simple cysts should be lined by a single layer of flattened or cuboidal epithelium.

Histopathology

Simple cysts vary considerably in size, ranging from less than 1 cm to greater than 10 cm. The majority are less than 2 cm in diameter, however (Tada et al., 1983). The wall is fibrous and of varying thickness and has no renal elements. The cyst lining is glistening and usually smooth and histologically is a single layer of flattened or cuboidal epithelium, and the cysts are filled with a clear, serous fluid. Because cysts are increasingly common with age, they have been considered an acquired lesion. Some cysts may be trabeculated by partial septa that divide the cavity into broadly interconnecting loculi. These septated simple cysts should not be confused with multilocular cysts. The cysts are often cortical and distort the renal contour, but they may be deep cortical or apparently medullary in origin. They do not communicate with the renal pelvis. The walls typically are thin and transparent but may become thickened, fibrotic, and even calcified, possibly from earlier hemorrhage or infection (Torres and Grantham, 2008).

Evaluation

Most simple cysts are identified incidentally. The clinician can safely make the diagnosis of a classic benign simple cyst by ultrasonography when the following criteria are met: **(1) absence of internal echoes, (2) presence of a sharply defined, thin, distinct wall with a smooth and distinct margin, (3) good transmission of sound waves through the cyst with consequent acoustic enhancement behind the cyst, and (4) a spheric or slightly ovoid shape** (Goldman and Hartman, 1990). If all of these criteria are satisfied, the chance that malignancy is present is negligible (Fig. 39.23; Lingard and Lawson, 1979; Livingston et al., 1981).

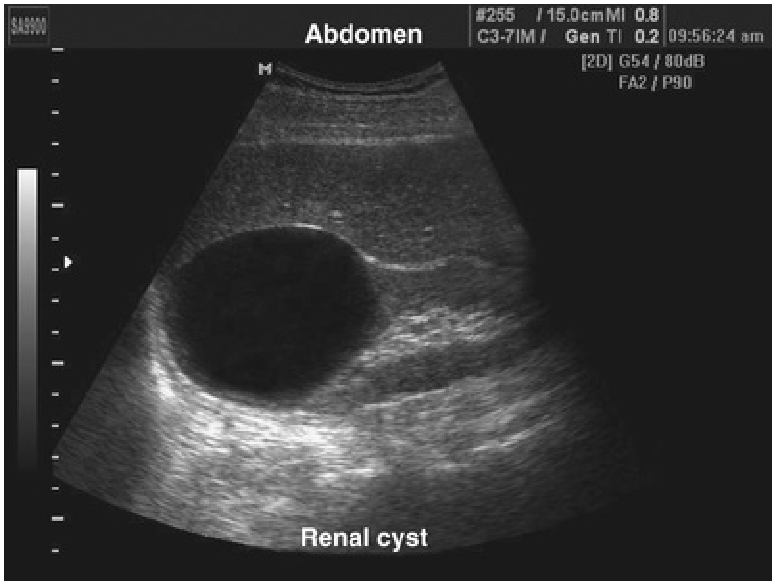

FIG. 39.23 Ultrasonographic appearance of a 4-cm simple renal cyst. This meets the definition of a true simple cyst: (1) absence of internal echoes; (2) sharply defined, thin, distinct wall with a smooth and distinct margin; (3) good transmission of sound waves through the cyst with consequent acoustic enhancement behind the cyst; and (4) spheric or slightly ovoid shape.

When some of these criteria are not met (e.g., when there are septations, irregular margins, calcifications, or suspect areas), further evaluation by CT, or perhaps needle aspiration or MRI, is indicated (Bosniak, 1986). A cluster of cysts is another indication for further study, because they may be hiding a small carcinoma. CT is better than ultrasonography in defining such a camouflaged lesion (Bosniak, 1986). Peripelvic cysts often require CT confirmation, because they frequently are interspersed among structures of the collecting system and hilum, which can create artificial echoes (Bosniak, 1986).

The CT criteria for a simple cyst are similar to those used in ultrasonography: (1) a sharp, thin, distinct, smooth wall and margin, (2) a spheric or ovoid shape, and (3) homogeneous content. When these criteria are respected, the accuracy of diagnosis of a simple cyst by CT approaches 100% (Fig. 39.24; McClennan et al., 1979). The density ranges from −10 to +20 HU, similar to the density of water, and no enhancement should occur after the intravenous injection of contrast medium.

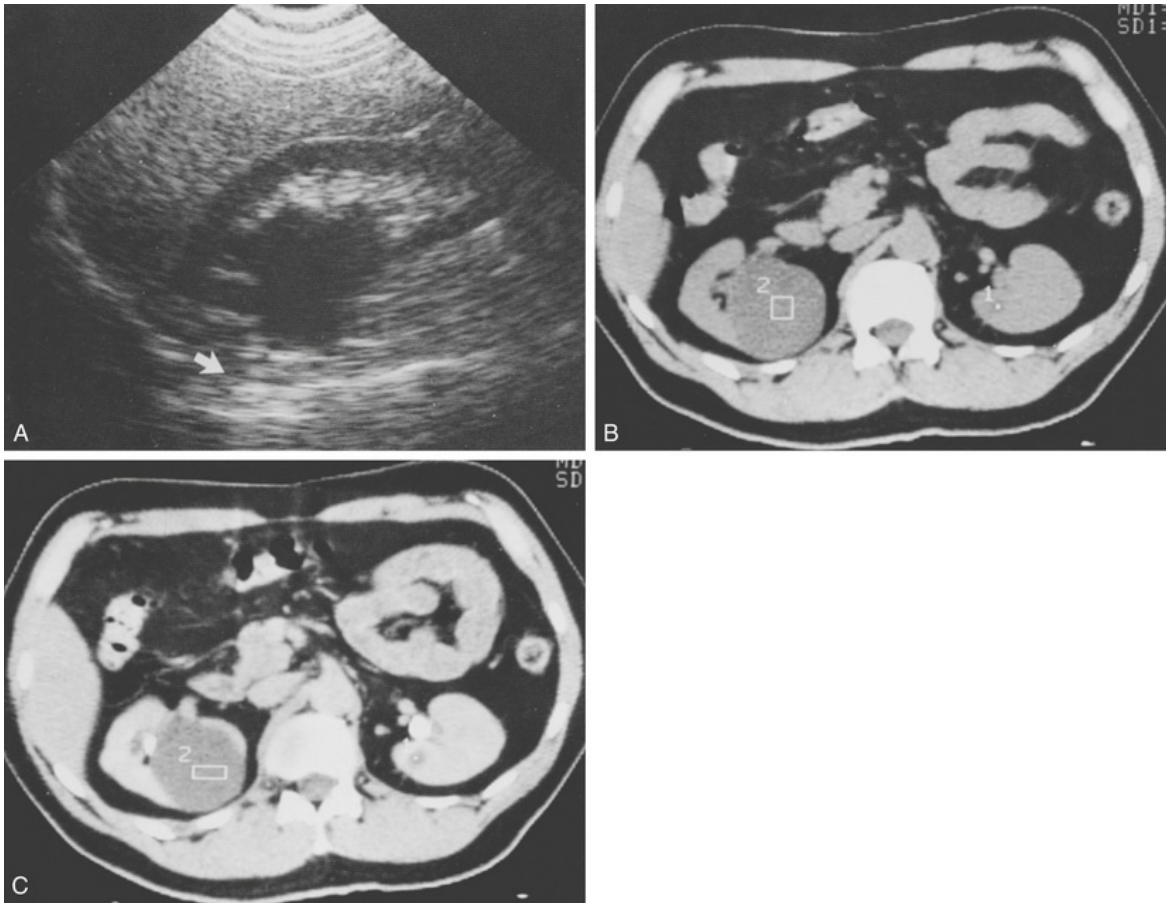

FIG. 39.24 A 56-year-old man with an indeterminate left renal cyst on renal ultrasonography. (A) Note the nonspheric, non–smoothly outlined sonolucent mass in the left kidney. However, there is good sound wave transmission through the cysts (acoustic enhancement), which is illustrated by the intensity (whiteness) of the ultrasonogram image behind the cyst *(arrow).* (B) On precontrast computed tomography (CT) scan, a very small cyst *(1)* is seen in the left kidney. The right renal cyst *(2)* that was identified on ultrasonography measures 17 HU. (C) After contrast agent administration, the CT value *(2)* was 16 HU, signifying no enhancement. CT values between −10 and +20 HU are characteristic of cysts. No enhancement with contrast agent confirms the diagnosis of a simple renal cyst. The small cyst *(1)* was not large enough for determining accurate CT values. (Courtesy G. Laungani, MD.)

When the cyst fluid is hyperdense (i.e., between 20 and 90 HU), the cyst still is likely to be a simple cyst if no enhancement occurs when intravenous contrast agent is injected and if the other criteria of CT and ultrasonography are met. Hyperdense cysts must be evaluated with narrow window settings to make sure that they are homogeneous. Other criteria that must be met to avoid further evaluation of hyperdense cysts (e.g., cyst puncture or exploration) include size (the lesion should be 3 cm or smaller) and location (at least one-fourth of the cyst's circumference should extend beyond the renal contour so that the smoothness of a good portion of the cyst can be evaluated) (Bosniak, 1991; Hartman et al., 1992). **Because cysts have no blood vessels and do not communicate directly with nephrons, they should not enhance; enhancement therefore implies vascular tissue or contrast medium mixing with fluid.** Enhancement of any nodular areas on the wall of the cyst or of a thickened septum within the cyst is taken as proof of vascularity within the lesion, and thus there should be a high index of suspicion for neoplasm.

When ultrasonographic or CT criteria are not met, conditions other than a simple cyst must be considered, such as complicated cysts (i.e., those containing blood, pus, or calcification) and cystic neoplasms. Cyst puncture and aspiration with or without contrast medium injection has been popular in the past, but with current imaging modalities the need for cyst puncture is very rare. The remaining indications for cyst puncture are (1) suspected infection, in which case puncture may be therapeutic as well as diagnostic, (2) the presence of low-level echoes on ultrasonography but a classic cyst on CT, and (3) a borderline lesion in a poor surgical candidate.

Two percent of simple cysts and 10% of RCCs contain calcium deposits, but calcification in simple cysts appears to be peripheral, whereas in tumors it is more central. When the cysts are numerous and bilateral, differentiation from ADPKD may be difficult if liver cysts are not also found. Because of the obvious implications, it is important to avoid a diagnosis of ADPKD in questionable cases unless a familial history consistent with autosomal dominant transmission can be documented or the diagnosis confirmed by genetic testing.

In children, several recent publications support the conclusion that stable (non-growing for 2 years) simple cysts require no additional follow-up unless otherwise indicated clinically (Bayram et al., 2014; Karmazyn, et al., 2015; O'Kelly et al., 2019; Rediger et al., 2019; Saltzman et al., 2018). They found that many renal cysts in children resolve spontaneously or show no growth on subsequent imaging. No cases of malignancy were noted in children found to have simple cysts and the rate of malignancy in complex cysts was also low. From their large study group, they have reasonably proposed that if a simple cyst is less than 15 mm in an asymptomatic patient less than 18 years old, then it is safe to repeat the ultrasound in 2 years and discharge the patient if stability of the cyst is demonstrated. They have continued to recommend surveillance only for patients with large (> 15 mm) cysts, complex cysts, and family history of inheritable cystic disease and patients with concomitant genitourinary anomalies.

MRI offers little information beyond that available from ultrasonography and CT, although it is more specific in identifying the nature of the cyst fluid. Marotti et al. (1987) found that if the fluid has low signal intensity (similar to that of urine) on T1-weighted images, the cyst is benign even if the wall is thick or septa are present. The T2-weighted images identify bloody fluid with an extremely bright image. Some have reported that MRI can lead to changes in category assignment in a significant proportion of cases, possibly because of its superior soft tissue and contrast resolution (Ferreira et al., 2016).

Classification

In an attempt to better categorize surgical and nonsurgical cysts in the kidney, Bosniak suggested a classification in 1986 that was clarified further in 1997 and modified by Israel and Bosniak in 2003 (Box 39.2). In addition, Wallis et al. (2008) suggested a modified Bosniak classification that can be used as a guideline to direct the need for surgical intervention in the pediatric population. They propose that in the absence of change or symptoms Bosniak category II cysts may be safely followed with periodic ultrasound imaging. Patients with Bosniak class III and class IV cysts have a significant chance of harboring malignancy, and surgical resection should be considered (Wallis et al., 2008). In addition, one recent study in children proposed a modified Bosniak classification and found that cystic renal lesions in children with a modified Bosniak class of I or II were most often benign, whereas class III or IVV lesions warranted surgical excision because more than 90% of masses harbored intermediate or malignant pathology. They concluded that the modified Bosniak classification system allows for a reasonable clinical risk stratification of pediatric cystic renal masses (Saltzman et al., 2018).

Box 39.2

Bosniak's Classification of Simple and Complex Cysts

Category I

Simple benign cyst with (1) good through-transmission (i.e., acoustic enhancement), (2) no echoes within the cyst, (3) sharply marginated smooth wall; requires no surgery

Category II

Looks benign with some radiologic concerns, including septation, minimal calcification, and high density; requires no surgery

Category II F

Although calcification in wall of cyst may even be thicker and more nodular than in category II, the septa have minimal enhancement, especially those with calcium; requires no surgery

Category III

More complicated lesion that cannot confidently be distinguished from malignancy, having more calcification, more prominent septation of a thicker wall than a category II lesion; more likely to be benign than malignant; requires surgical exploration and/or removal

Category IV

Clearly a malignant lesion with large cystic components, irregular margins; solid vascular elements; requires surgical removal

Category I cysts are the typical benign cysts. Category II cysts are benign cystic lesions that are minimally complicated, such as by septations, small calcifications, infection, or high density, and do not require surgery. For example, when all the criteria for a simple cyst are met, except that a fine line of calcification or a short segment of slightly thickened calcification is seen in the wall or septa, the lesion should be considered a benign cyst, and exploration is not required. Another example is the cyst with fine traversing strands, perhaps containing calcium. In this case, exploration is not required unless the septa are numerous, irregular, or thick.

Category II F cysts (Israel and Bosniak, 2003) are complex cysts that cannot be classified as either category II or III. These lesions may contain increased calcification. The calcification may even be thicker and nodular, but although the septa may have minimal enhancement, those septa with calcium do not enhance. Calcification seems to represent a less significant finding in making a lesion suspicious as a malignancy than previously thought. More focus is placed on tissue enhancement. There is little concern if calcification increases with time but much concern if the wall or septa becomes thicker or irregular. **Category II F cysts do not necessarily require surgical exploration** (Fig. 39.25; Israel and

Bosniak, 2003). However, more recent reports have shown that malignant progression can occur in 10.9% of cases and requires close follow-up (Hindman et al., 2014).

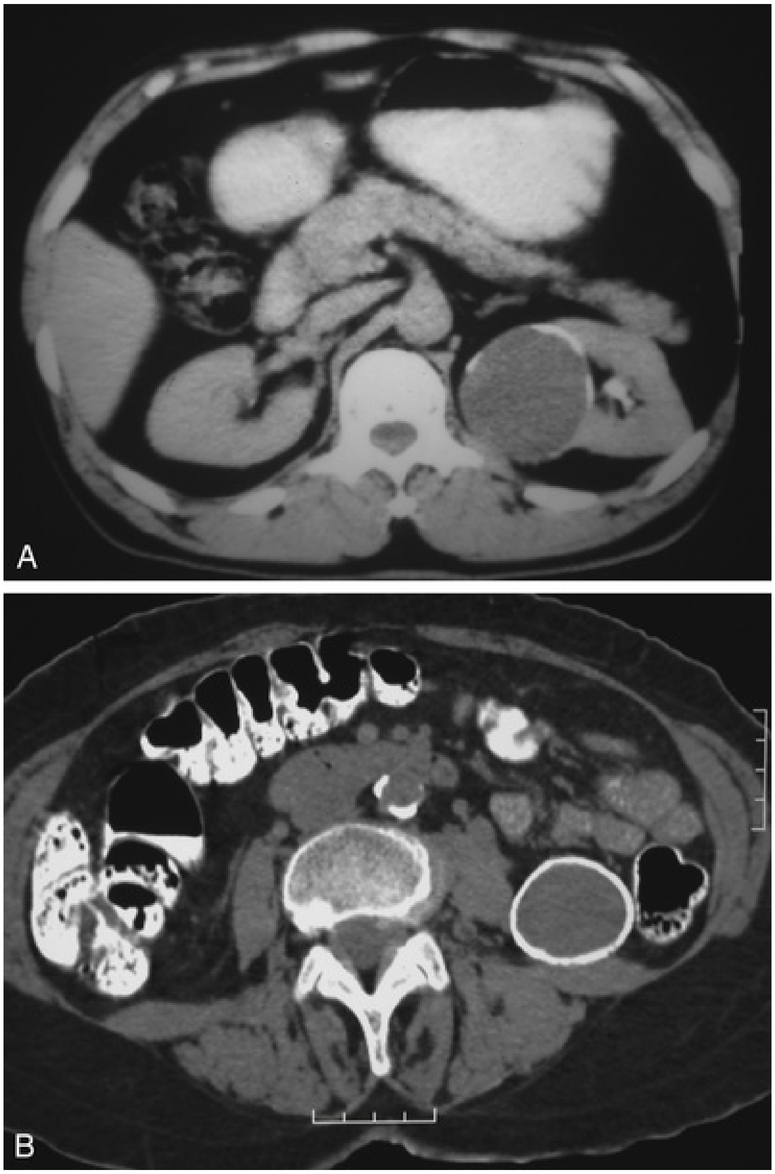

FIG. 39.25 (A and B) Two examples of Bosniak category II F cysts with diffuse calcification but no enhancement of septa on computed tomography. (Courtesy Jeffrey Newhouse, MD.)

Category III cysts are more complicated lesions with radiologic features that are also seen in malignancy. One example is the lesion with more extensive calcification, especially if the wall is not pencil-point thin or is

irregular. Other category III cysts are those with septations, suggesting a multilocular cystic lesion, or chronic infection with a thickened wall. These lesions are more problematic and require a surgical approach that is individualized. In some cases, the clinician may consider violating the Gerota fascia to expose the kidney for examination of the lesion or partial nephrectomy.

Bosniak category IV lesions are cystic malignant tumors and are dealt with as such, namely, by radical nephrectomy.

Treatment and Prognosis

Once malignancy has been ruled out, surgical intervention for an asymptomatic cyst is not indicated (Bartholomew et al., 1980; Gordon et al., 1979; Ravden et al., 1980; Siegel and McAlister, 1980). Large renal cysts may cause abdominal or flank pain, although this pain may be caused by a coexisting problem (e.g., nephrolithiasis), and other sources of pain should be ruled out. Other symptoms that may arise as a result of simple cysts are pain resulting from hemorrhage into the cyst or calyceal or infundibular obstruction caused by cyst impingement. In rare cases, hypertension may occur, presumably from cyst compression causing segmental renal ischemia of the surrounding renal parenchyma. Cyst infection is a rare but potentially severe complication, with patients demonstrating fever, flank pain, and often a sympathetic pleural effusion (Torres and Grantham, 2008). Most of these patients are women, the most common pathogen is *Escherichia coli*, and urine cultures can often be negative.

Treatment of the simple cyst must thus be directed to the symptomatology. When a benign simple cyst causes pyelocalyceal obstruction or hypertension, the problem may be corrected either surgically, by unroofing the cyst, or percutaneously, by aspirating the fluid and perhaps injecting a sclerosing agent, particularly if fluid has reaccumulated after an earlier aspiration. Several sclerosing agents have been used, including glucose, phenol, iophendylate (Pantopaque), bismuth phosphate, and absolute ethanol, but none has been sufficiently impressive for its use to become dominant (Holmberg and Hietala, 1989). Infected cysts must be drained and appropriate antibiotics given. Percutaneous resection, intrarenal marsupialization (Hubner et al., 1990; Hulbert and Hunter, 1990; Meyer and Jonas, 1990), and laparoscopic unroofing (either transperitoneally or retroperitoneally) are reasonable options for the treatment of symptomatic simple cysts.

Unilateral renal cystic disease is characterized by cysts of varying size
